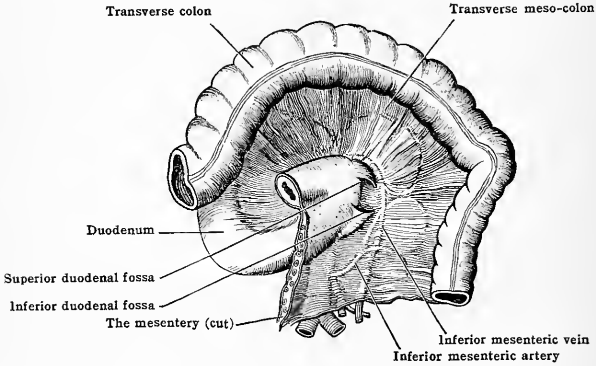
Interior of the duodenum.—The interior of the first part of the duodenum is smooth. The pylorus is often somewhat invaginated, much in the same way that the uterus projects into the vagina (fig. 908). On account of this arrange-

Fig. 923.—Duodenal Fossæ and Folds. Paraduodenal fossa is not shown. (After Cunningham.)



ment (which renders the complete emptying of the cavity somewhat difficult) and also on account of the distensibility of this portion, it usually shows up very distinctly in radiographic pictures as a 'cap' to the pyloric end of the stomach during digestion. In the lower portions of the duodenum, transverse ridges or folds of the mucosa appear (fig. 922) which are also apparent in radiographs occasionally. On the medial wall of the descending portion, posteriorly, about half-way down, is a more or less distinct *longitudinal fold* [plica longitudinalis duodeni], toward the lower end of which is a small elevation, the bile papilla or *papilla major* [papilla duodeni], upon which open the common bile duct and the pancreatic duct, either separately or by a common aperture (fig. 922). Above the papilla there is usually a prominent *hood-like fold* (valvula connivens), and below it a variable fold or *frænum* which forms a continuation of the plica longitudinalis. About 2 cm. (.9 to 3.5 cm., Baldwin) above and in front of the bile papilla there is a second, smaller, rounded *papilla minor*, upon which the accessory pancreatic duct (of Santorini) ends.

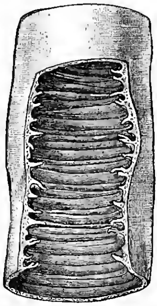
The minute structure, vascular relations, development, variations, etc., of the duodenum will be considered later, with those of the small intestine as a whole.

THE JEJUNUM AND ILEUM

The mesenteric portion of the small intestine is divided into an upper half (or two-fifths), the *jejunum,* and a lower half (or three-fifths), the *ileum.* Although the character of the gut changes considerably from the upper end of the jejunum to the lower end of the ileum, the transition is gradual, and there is no definite line of demarcation. In general, the jejunum is somewhat wider, has thicker walls, is more vascular and has a more complicated mucosa. The lymphoid organs (Peyer's patches) are, however, characteristic of the ileum.

The **jejunum** begins at the duodeno-jejunal flexure. The first coil is variable in direction, being found (in order of frequency) as follows: (1) downward, forward and to the left; (2) directly forward and downward; (3) to the left, then downward; (4) forward and to the right (Harman). Some further details as to the position of the various succeeding coils are given later under the development of the intestine (figs. 930, 931). While there is considerable individual variation, it is true in general that the coils of *jejunum* occupy the upper and left portion of the body cavity, while those of the *ileum* occupy the lower and right side, the lower portion lying in the pelvic cavity. The ileum finally passes upward over the pelvic brim to the right iliac fossa where it terminates in the ileo-cæcal orifice.

Fig. 924.—Portion of the Small Intestine, Laid open to Show the Plicæ Circulares. (Brinton.)



The **mesentery** [mesenterium] is a fan-shaped fold extending from the duodeno-jejunal flexure to the ileo-cæcal junction. It is composed of a double layer of peritoneum which encloses and supports the jejunum and ileum and their vessels, connecting them with the abdominal wall. The *root* of the mesentery [radix mesenterii] or parietal attachment, is only about 15 cm. long, corresponding to a line extending from the duodeno-jejunal flexure obliquely downward and to the right, across the transverse duodenum, the great vessels and the vertebral column to the ileo-cæcal junction (fig. 905).

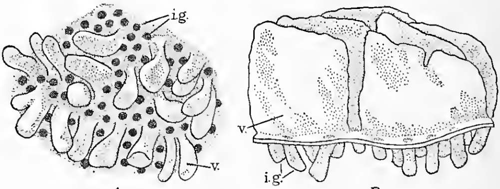
The *visceral* attachment of the mesentery to the intestine, corresponding to the length of the jejuno-ileum, is nearly 7 metres long, and is thinner than at the root. The *width* of the mesentery, measured from parietal to visceral attachment, varies somewhat in different parts of the canal, the average being 18 or 20 cm. (ranging from 15 to 22.5 cm.). It is narrow above (also at the lower end), but reaches its full width about 30 cm. below its upper end. Between the two peritoneal layers of the mesentery is a third layer [lamina mesenterii propria] containing the superior mesenteric vessels (arteries, veins and lymphatics) with their branches and accompanying nerves, the small mesenteric lymph-nodes (50 to 100 in number), and a variable amount of fibro-adipose connective tissue.

Minute anatomy.—The small intestine has the four typical layers,—mucosa, submucosa, muscularis and serosa (figs. 927, 928). They are, in general, somewhat similar in structure to those of the stomach (fig. 910), excepting the mucosa.

The **mucosa** is lined with a simple cylindrical epithelium, underneath which is a fibrous *lamina propria,* limited externally by a *muscularis mucosæ,* as in the stomach. The muscularis mucosæ sends slender muscular bundles upward into the villi. The inner surface of the mucosa (fig. 924) presents numerous coarse, closely set, transverse folds [plicæ circulares]. These are permanent, crescentic folds, involving both mucosa and submucosa, and usually extending one-half to two-thirds of the way around the lumen. They often branch and anastomose, sometimes forming circles or spirals. The largest exceed 5 cm. in length and 3 mm. in width. The plicæ circulares are absent from the first part of the duodenum, but become well-marked in the descending portion (fig. 922). They are largest and best developed in the lower duodenum and upper half of the jejunum, below which they gradually become smaller (fig. 924) and disappear at the lower end of the ileum.

The digestive and absorptive surface of the small intestine is further greatly increased by multitudes of small processes, the *villi* (figs. 925, 927), which give the mucosa a velvety appearance. They are largest (.5 to .7 mm. in height) and most numerous in the duodenum and jejunum, where they are typically leaf-shaped, and gradually become smaller, scattered and conical in the ileum. The villi are much reduced in distention of the intestine, and may even be temporarily obliterated. Between the bases of the villi there open short, simple tubular glands—the crypts of Lieberkuehn [gl. intestinales], whose fundus cells (of Paneth) probably secrete digestive enzymes. In the duodenum there are found, in addition, the larger tubulo-

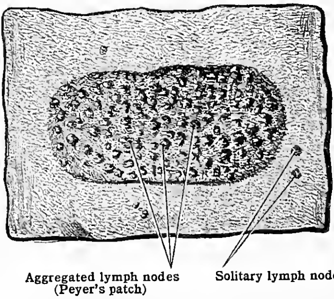
Fig. 925.—*A*, Surface View of the Hardened Mucosa of the Small Intestine. (After Kölliker.) *B*, Side View of a Wax Reconstruction of the Epithelium in the Human Duodenum. (Huber.) *i.g.*, Intestinal gland. *v.*, Villus.



racemose glands of Brunner [gl. duodenales], which occupy the submucosa, and are especially numerous in the upper portion of the duodenum. They are purely mucous in character according to Bensley, although Oppel describes granular cells, similar to Paneth cells, which may secrete digestive enzymes.

Scattered over the whole of the mucous membrane of the small intestine are numerous small lymph-nodules, the larger of which extend into the submucosa; these are the so-called *solitary glands* [noduli lymphatici solitarii]. Aggregations of lymph-nodules, known as *Peyer's patches* [noduli lymphatici aggregati], situated in the mucosa and submucosa, are found in the ileum especially toward the lower end (fig. 926). They are oval, from 1.2 to 7.5 cm. in length and about 1 to 2.5 cm. in breadth, and are placed in the long axis of the bowel along a line most remote from the mesentery. They are variable in number, the average being about 20 to 30.

Fig. 926.—Surface View of the Mucosa of the Ileum, Showing Aggregated Lymph Nodes (Peyer's Patch). (From Toldt's Atlas.)



The **submucosa** is in general a loose areolar layer containing vascular and sympathetic plexuses (figs. 927, 928). The **muscularis** is composed of smooth muscle arranged in the two typical layers,—a thinner, outer longitudinal and a thicker, inner circular,—both of which become thinner toward the lower end of the ileum. The **serosa** is typical in structure, the squamous epithelial covering being absent in the retroperitoneal areas of the duodenum.

Blood-supply of the small intestine.—The small intestine receives its blood from the superior mesenteric artery and a branch coming indirectly from the hepatic, the superior pancreaticoduodenal. The superior mesenteric artery runs between the layers of the mesentery and gives off six or seven relatively large branches and a variable number of smaller branches. The first two or three of the larger branches divide into an ascending and a descending branch, which join above and below with the corresponding branches of the continguous arteries, forming thus a single row of arches. From about the beginning of the second quarter of the small

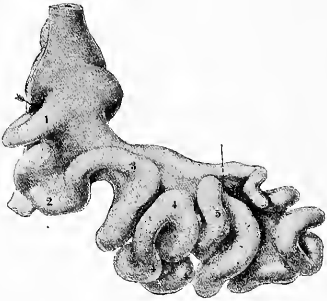
intestine a second tier of arches, formed in a similar manner, is often noted, and below the middle of the jejuno-ileum more than two tiers of arches may be present the complexity of the arches increasing, while the size of the vessels diminishes. From the convex border of the most distally placed arches there pass to the intestine straight branches, so-called vasa recta. Near the beginning of the jejunum these are numerous and large, and have a length of about 4 cm., and are quite regular. After the first third of the intestine is passed the vasa recta become smaller and shorter, and toward the lower end of the ileum they become short and irregular and are often less than 1 cm. in length. (Dwight.) The blood is returned by means of the superior mesenteric vein, which, with the splenic vein, forms the portal. The vascular arrangement in the intestinal wall is shown in fig. 928.

The **lymphatic** vessels form a continuous series, which is divided into two sets—viz., that of the mucous membrane and that of the muscular coat. The lymph-vessels of both sets form a copious plexus (fig. 928). The efferent lymphatic vessels form the so-called lacteals, which pass through the mesenteric lymph-nodes, finally reaching the cisterna (receptaculum) chyli.

The nerves.—The small intestine is supplied by means of the superior mesenteric plexus which is continuous with the lower part of the cœliac (solar) plexus. The branches follow the blood-vessels, and finally form two plexuses: one (Auerbach's or myenteric) which lies between the muscular coats; and another (Meissner's) in the submucous coat. The nerve fibres are chiefly from the sympathetic, partly from the vagus.

Development of the small intestine.—As the intestine is being separated from the yolk-vesicle it forms at first a relatively straight tube, and as the tube elongates there is formed a single primary loop, situated in the sagittal plane of the embryo, which loop extends into the cœlom of the umbilical cord; to its summit is attached the constricted attachment of the yolk-vesicle, the yolk-stalk (fig. 929). This primary loop of the intestine, as it elongates, turns on an axis, so that its caudal portion turns toward the left and its cephalic portion toward the right. We may then speak of a right and a left half of the loop. Near the top of the left half of the loop there is noted an enlargement which marks the cæcum, the greater part of the left

FIG. 929.—MODEL OF STOMACH AND INTESTINE of HUMAN EMBRYO 19 MM. LONG. The figures on the intestine indicate the primary coils (× 16). (Mall.)



half of the loop forming, therefore, the large intestine, while the right half of the loop forms the small intestine. In the further growth of the loop the right half elongates more rapidly than the left half, so that the cæcum is no longer found in the middle of the loop. In an embryo of the fifth week, as noted by Mall, whose account is here followed closely, 'the right half of the loop has a number of small bends in it, which are of great importance in the further development of the intestine.' These small bends or loops he has marked with the numbers 1, 2, 3, 4, 5, 6. (See figs. 929, 930, 931.) The first of these bends is primarily not clear, appearing as a portion of the pyloric end of the stomach; however, it is recognised by the fact that the ducts of the liver and pancreas terminate in it, marking it as the duodenum. The omphalo-mesenteric veins and arteries, the future superior mesenteric vessels, pass through the middle of the mesentery of the large primary loop and pass over the sixth bend or secondary loop, to which is also attached the yolk-stalk. With the elongation of the intestine these six bends or loops become accentuated and acquire secondary loops or coils, nearly all of which are still found in the cœlom of the umbilical cord, but even with this more complicated coiling of the intestine the six primary divisions may be clearly made out. (See fig. 929.)

The large intestine, the left half of the large primary loop, lies in the sagittal plane of the embryo and does not grow as rapidly as the small intestine, and while this is acquiring the secondary coils, the whole mass rotates about the large intestine as an axis. 'By this process the small intestine is gradually turned from the right to the left side of the body, and in so doing is rolled under the superior mesenteric artery. This takes place while the large intestine has an antero-posterior direction and before there is a transverse colon.' (Mall.) With the return of the small intestine from the umbilical cœlom to the peritoneal cavity, which occurs apparently quite suddenly and during the middle of the fourth month, the cæcum comes to lie in the right half of the abdominal cavity, just below the liver; the greater portion of the remainder of the large intestine then lies transversely across the abdominal cavity as the transverse colon. The six groups of loops of the small intestine may still be recognised, the loops of the upper part of the small intestine having rolled to the left of the superior mesenteric artery, while the loops which were formerly in the cord are found in the right side of the abdominal cavity. It is not difficult to trace these six groups of loops through the later stages of fœtal life to the new-born, and thence to the adult stage. In the adult, as also through the various stages of development, loop 1 forms the duodenum. From the primary groups of coils marked 2 and 3 are developed the greater part of the jejunum, arranged in two distinct groups of loops, situated in the left hypochondriac region. The part of the intestine developed from group 4 of the primary coils passes across the umbilical region to the right upper part of the abdomen. That part developed from group 5 of the primary coils recrosses the median line to the left iliac fossa, while that part derived from group 6 of the primary coils is found in the false pelvis and the lower part of the abdominal cavity between the psoas muscles. (Mall.) Figs. 900, 901, 930 may serve to make clear these statements. They present what may be regarded as the normal arrangement of the small intestine, having been found 21 times in 41 cadavers examined. Variations from this arrangement occur; the great majority of such variations are, however, not of sufficient importance to require special mention.

According to Johnson (upon whose descriptions the following account is based), there is in embryos of 13 mm. to 23 mm. a formation of vacuoles in the duodenal epithelium, which

Fig. 930.—Model Showing Course of Intestine, Made from Same Cadaver from which Fig. 931 was Drawn. (Mall.)

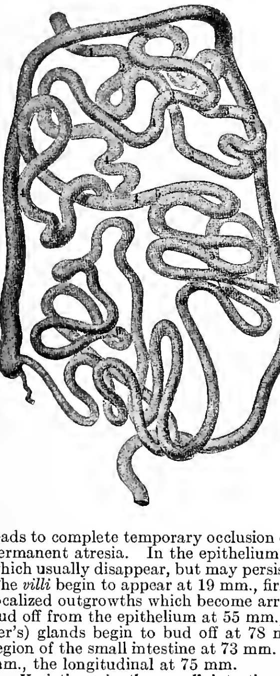


Fig. 931.—The Usual Position of the Intestine in the Abdominal Cavity. The numbers in the figure mark the parts which are homologous with the primary bends and groups of coils numbered from 1 to 6. (Mall.)

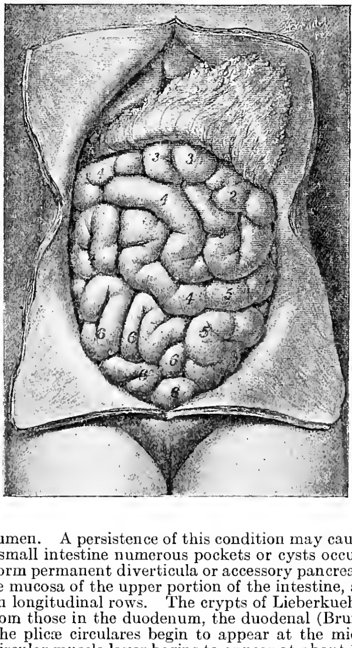


leads to complete temporary occlusion of the lumen. A persistence of this condition may cause permanent atresia. In the epithelium of the small intestine numerous pockets or cysts occur, which usually disappear, but may persist and form permanent diverticula or accessory pancreas. The *villi* begin to appear at 19 mm., first in the mucosa of the upper portion of the intestine, as localized outgrowths which become arranged in longitudinal rows. The crypts of Lieberkuehn bud off from the epithelium at 55 mm., and from those in the duodenum, the duodenal (Brunner's) glands begin to bud off at 78 mm. The plicæ circulares begin to appear at the mid-region of the small intestine at 73 mm. The circular muscle layer begins to appear at about 12 mm., the longitudinal at 75 mm.

Variations in the small intestine.—Although relatively fixed in position, the *duodenum* is quite variable in form. The **C**-shape previously described is the most common. When the pylorus and the duodeno-jejunal flexure are approximated, the form is nearly circular. When the two ends are more widely divergent, it approaches a **U**-form. Not infrequently, the inferior portion ascends abruptly from the inferior angle, giving a **V**-form. Finally, the terminal ascending portion may be very small or absent, in which case the duodenum approaches an **L**-form. Variations in the position of the various coils of the jejunum and ileum have already been discussed. The lymph-nodules, including Peyer's patches, like all lymphoid structures, are prominent during youth, but become atrophied in old age.

Meckel's diverticulum, which represents a derivation from the embryonic yolk stalk and sac, is found in about 2 per cent. of all adults. It is a blind tube or diverticulum of variable size, usually approaching the intestine in width and averaging 5 cm. in length (ranging from 1 cm. to 13 cm.). Its attachment to the intestine varies from 15 cm. to 360 cm. (average 80 cm.) above the cæcum. It is usually attached opposite the mesentery. It may end freely, but is occasionally adherent to adjacent intestinal coils or connected with the anterior abdominal wall by a cord or band-like process.

Other diverticula of variable size and number may occur, usually along the mesenteric border of the intestine. They may be either congenital (probably from the embryonic pockets previously mentioned) or acquired. They occur most frequently in the duodenum (found by Baldwin in 15 of 105 cases) where they are usually associated with the openings of the bile and pancreatic ducts.

Comparative.—The comparative anatomy of the small intestine will be discussed later together with that of the large intestine.

THE LARGE INTESTINE

The **large intestine** [intestinum crassum] is that part of the alimentary canal which extends between the ileum and the anus. It is divided into the following parts: Cæcum, ascending, transverse, descending, and sigmoid colon, and rectum. It is so arranged as to surround the small intestine, making a circuit around the abdominal cavity from right to left (fig. 899). The *cæcum* lies in the right iliac fossa; thence the colon passes vertically upward on the right side (*ascending colon*) until the liver is reached. Here it forms a more or less rectangular bend (the right colic or hepatic flexure), and then passes transversely across the belly (*transverse colon*) below the stomach. It then reaches the spleen, where it makes a second sharp bend (the left colic or splenic flexure), and, passing vertically downward on the left side (*descending colon*), reaches the left iliac fossa. At this point it forms the loop of the sigmoid colon, and finally passes through the pelvis as the rectum (fig. 906). The large intestine is much larger in diameter than the small intestine, and is not so much convoluted. Excepting the dilated portion of the rectum, it is wider at the beginning than at the end. It varies in width at different parts from 3 to 8 cm. The length from the root of the appendix or tip of the cæcum to the point where the meso-colon ends is, in the male, about 140 cm., and in the female about 130 cm. The average total length, including the rectum, is about 150 cm. (5 ft.). The extremes found are 100 to 200 cm.

The large intestine, in all parts except the rectum, has a peculiar arrangement of its walls, which gives it a very different appearance from the small intestine. It is *sacculated*, and the sacculations [haustra] are produced by the gut having to adapt its length to three shorter muscular bands which run the course of the intestine. These bands, which are about 12 mm. wide and 1 mm. thick, are really the longitudinal fibres of the muscular wall, which are chiefly collected along three lines (fig. 935). One band [tænia mesocolica], corresponding to the attachment of the mesocolon, is posterior on the transverse colon, and postero-median on the ascending and descending colons. A second band [tænia omentalis] is antero-superior on the transverse colon, elsewhere postero-lateral. The third band [tænia libera] is free; it is inferior on the transverse colon, anterior elsewhere. All these bands start on the cæcum at the vermiform process, and spread out to form a uniform layer on the rectum. Between the sacculations are *semilunar folds* [plicæ semilunares coli], which involve the entire thickness of the intestinal wall, forming crescentic ridges of the mucosa which project into the lumen (figs. 932, 935). Along the free surface of the colon, especially near the tæniæ, are numerous small appendages [appendices epiploicæ], which are pouches of peritoneum containing fat (fig. 906).

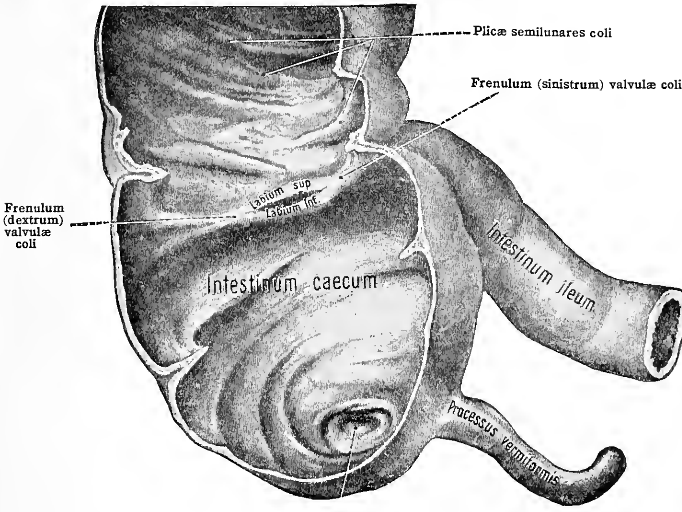
The cæcum.—The cæcum [intestinum cæcum] is a *cul-de-sac* forming the first part of the large intestine. It is defined as that part of the colon which is situated below the entrance of the ileum. Its breadth is about 7.5 cm., and its length about 6 cm. (Fig. 932).

There is usually a more or less well-marked constriction opposite the ileo-cæcal orifice marking the boundary between cæcum and colon. The cæcum itself also frequently presents a constriction dividing it into two sacculations.

It lies in the right iliac fossa, and is usually situated upon the ilio-psoas muscle, and so placed that its apex or lowest point is just projecting beyond the medial border of that muscle (figs. 899, 906). It is usually entirely enveloped in peritoneum, and is free in the abdominal cavity, but more or less attached in about 10 per cent. of all cases. The apex of the cæcum usually corresponds to a point a little to the medial side of the middle of the inguinal ligament. Less frequently the cæcum will be found to be in relation with the iliacus muscle only; or the bulk of it will lie upon that muscle, while the apex rests upon the psoas. In a number of cases the cæcum is entirely clear of both psoas and iliacus muscles, and hangs over the pelvic brim, or is lodged entirely within the pelvic cavity. Sometimes the cæcum may pass even to the left of the median line of the body.

This part of the colon is liable to considerable variation.

Fig. 932.—Interior of the Cæcum, Anterior View. (Rauber-Kopsch.)

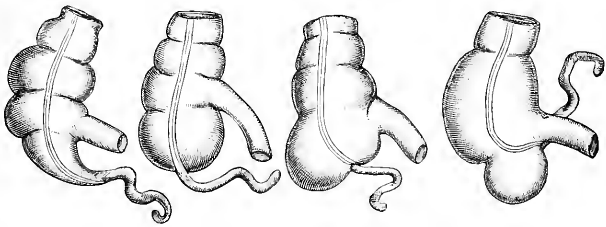


Its *variations* in form may be described under *four types:*

1. The fœtal type is conical in shape, the appendix arising from the apex, and forming a continuation of the long axis of the colon. The three muscular bands which meet at the appendix are nearly at equal distances apart (fig. 933, A). When the cæcum is empty and contracted it tends to approach this type.

2. The second form is more quadrilateral in shape than the last; the three bands retain their relative positions; the appendix appears between two bulging sacculi, instead of at the summit of a cone (fig. 933, B).

Fig. 933.—The Four Types of Cæcum. (Treves.)



3. In the third type, that part of the cæcum lying to the right side of the anterior band grows out of proportion to that part to the left of the band. The anterior wall becomes more developed than the posterior, so that the apex is turned so much to the left and posteriorly that it nearly meets the ileo-cæcal junction. A false apex is formed by the highly developed part to the right of the anterior band. This is the usual cæcum found (fig. 933, C).

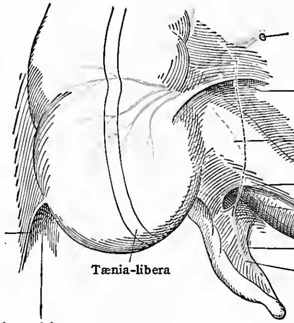
4. In the fourth type, the development of the part to the right of the anterior band is excessive, while the segment to the left of the band has atrophied. In this form the anterior band runs to the inferior angle of junction of the ileum with the cæcum. The root of the appendix is posterior to that angle. There is no trace of the original apex, and the appendix appears to spring almost from the ileo-cæcal junction (fig. 933, D.)

The ileo-cæcal valve.—The ileo-cæcal valve [valvula coli] is situated at the entrance of the ileum into the large intestine at the upper border of the cæcum, on the posterior aspect and toward the medial side (fig. 932). The valve usually lies nearly opposite the middle of a line from the anterior superior iliac spine (left) to the umbilicus. The ileum passes from below upward and toward the right, and terminates with a considerable degree of obliquity. The valve is formed by two lip-like folds projecting into the large intestine, the upper [labium superius], and the lower [labium inferius]. They are a little oblique. The opening between them takes the form of a narrow transverse slit about 1.2 cm. in length. At the ends of the slit the valves unite and are prolonged at either end as a ridge [frenulum valvulæ coli] partially surrounding the intestine.

Villi cover that surface of the folds looking toward the ileum; the surface toward the large intestine is free from villi. In the formation of this valve the longitudinal muscular fibres pass across from the ileum to the large intestine without dipping down between the two layers of each fold. The circular muscular fibres, on the other hand, are contained between the mucous and submucous layers which form these folds.

The efficiency of the valve in preventing the return of fæces is due largely to its oblique position. (Symington.)

Fig. 934.—Cæcum, Vermiform Process, and End of Ileum, with the Blood-supply and the Neighbouring Fossæ. (Woolsey, after Merkel.)



Ileo-cæcal fossæ.—About the cæcum, and especially in the vicinity of the ileo-cæcal junction, are certain fossæ collectively known as the ileo-cæcal fossæ. Two only appear to be fairly constant, although a third is now and then present.

The first, the *superior ileo-cœcal* or *ileo-colic fossa,* is formed by the passage across the junction of the cæcum and ileum of the anterior cæcal artery, a branch of the ileo-colic artery, which produces a fold of peritoneum [plica ileocolica] limiting a pouch. It is on the anterior aspect of the ileo-colic junction, and the pouch opens downward (figs. 906, 934). It is present in about one-third of all cases.

The second fossa is not quite so simple. If the cæcum be turned upward so as to expose its posterior surface as it lies *in situ,* and if the appendix be drawn down so as to put its mesentery on the stretch, a peculiar fold will be found to join that mesentery (fig. 934). This fold arises from the border of the ileum opposite the insertion of its mesentery. It then passes over the ileo-cæcal junction on its inferior aspect, is adherent to the cæcum, and finally joins the surface of the mesentery of the appendix. This fold is peculiar in the absence of any visible vessels, and is often known as the 'bloodless fold of Treves.' Between it and the appendix there is an almost constant fossa, the *inferior ileo-cœcal fossa.* It is usually large, admitting two fingers, and occurs in nearly 85 per cent. of all cases. It is bounded on one side by the small intestine, and on the other by the cæcum. The appendix is occasionally found in the fossa.

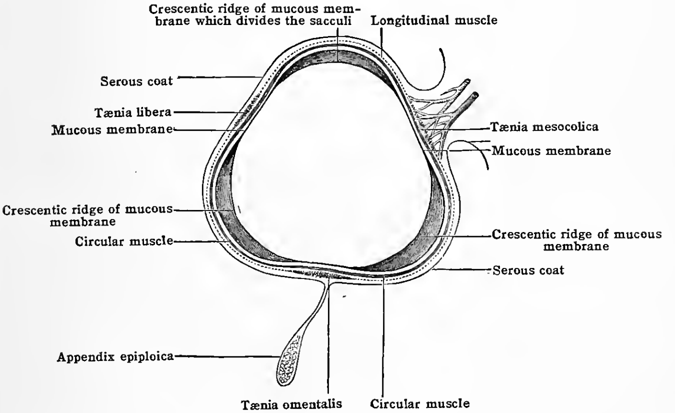
The *subcœcal* or *retrocolic* fossa is behind the cæcum and is found in about ten per cent. of all cases. It may extend for some distance behind the ascending colon. The appendix may be lodged in this fossa.

Paracœcal fossæ rarely occur, at the side of the cæcum.

Variations.—In addition to variations already mentioned the cæcum may vary in its general development. It is sometimes small and insignificant; in other cases it reaches a large size. It may be so rotated that the ileum passes behind the colon and opens on the right side. The posterior part has been seen much more developed than the anterior, so that the ileum has entered from the front, and the appendix has come off from the anterior wall. The cæcum may remain undescended, and be found just under the liver or in the vicinity of the umbilicus. In case the rotation of the embryonic intestinal loop fails to occur (which rarely happens) the cæcum may remain permanently upon the right side. If the normal process of adhesion fails to occur, the cæcum and colon, along with the small intestine, may remain suspended from the mid-dorsal line by the primitive *mesenterium commune*. Or any of the intermediate stages of partial adhesion may persist.

The vermiform process.—Attached to what was originally the apex of the cæcum is a narrow, blind tube, the *vermiform process* [processus vermiformis] or *appendix*. It comes off at a variable distance (usually about 2.5 cm.) below the ileo-cæcal valve on the postero-medial aspect of the cæcum, though sometimes from the lower end of the cæcum, or elsewhere. On the interior, at the point where it joins the cæcum (fig. 932), there is a slight inconstant valve [valvula processus vermiformis]. The appendix joins the cæcum at the point where the three

Fig. 935.—Cross-section of the Ascending Colon. (Allen Thomson.)



tæniæ meet, and the anterior tænia forms the best guide to this point. In the adult, the average length of the appendix is between 8 cm. and 10 cm., the extremes being 2 cm. to 25 cm. It is usually much twisted and coiled upon itself. Its direction is most frequently downward toward the pelvic cavity, or upward and medialward behind the ileum in the direction of the spleen. It occasionally turns lateralward, or more rarely upward behind the cæcum.

The vermiform process does not have a true mesentery, but usually (in about 90 per cent. of cases) is provided with a falciform fold [mesenteriolum] of peritoneum, continuous with the left (lower) layer of the mesentery of the ileum (figs. 906, 934).

In general outline this fold of peritoneum is triangular. In the adult it does not extend along the whole length of the tube. It is, in fact, too short for the appendix, and it is this that accounts for the twisted condition of this process. Along the free margin of the fold runs a branch of the ileo-colic artery (fig. 934).

The ascending colon.—The ascending colon [colon ascendens] (figs. 906, 914) extends in the right lumbar (lateral abdominal) region from the cæcum to the inferior surface of the liver, lateral to the gall-bladder, forming there the right colic [flexura coli dextra] or hepatic flexure. Its average length is about 20 cm. (or somewhat less when measured *in situ*). It is covered by peritoneum in front and on the side (fig. 902), but in a certain proportion of cases (26 per cent. according to Treves) this part of the large intestine is connected with the posterior wall of the abdomen by a meso-colon (usually very short) and is therefore surrounded by peritoneum. Connected with the ascending colon is sometimes found a fold of peritoneum, extending from the right side of the gut to the abdominal wall at a little above the level of the highest part of the iliac crest. It forms a shelf upon which rests the extreme right margin of the liver. It might be called the *sustentaculum hepatis.*

The ascending colon is in relation *behind* with the right kidney, and the iliacus and quadratus lumborum. *In front* are some of the coils of the ileum (fig. 899), separating it from the anterior abdominal wall.

The transverse colon.—The transverse colon [colon transversum], smaller in diameter than the ascending, extends from the lower surface of the liver to the spleen. Its average length is from 40 to 50 cm. It describes an arch with its convexity forward and downward. It crosses through the umbilical region from the right hypochondrium to the left hypochondrium (figs. 899, 906, 914).

In the majority of cases the superficial part of the colic arch—as seen before the viscera are disturbed—is either in whole or in greater part above a straight line drawn transversely across the body between the highest points of the iliac crest. In about one-fourth of all cases it lies, in whole or in greater part, below this line.

Certain remarkable bends are sometimes formed by this part of the bowel. The bending is always in the same direction, namely, downward, and is usually abrupt and angular. The apex of the **V** or **U**-shaped bend thus formed may reach the pubes. This bend appears to be due to two distinct causes: namely, long-continued distention, on the one hand, and congenital malformation on the other.

The transverse colon is in relation *above* with the liver and gall-bladder, the stomach, and at its left extremity with the spleen. The second portion of the duodenum passes *behind* it. *Below* are the coils of the small intestine. It is almost completely surrounded by peritoneum, being connected with the posterior abdominal wall (chiefly the anterior border of the pancreas) by the transverse mesocolon. This is usually lacking on the right of the mid-line, however, where the colon crosses the descending duodenum and the head of the pancreas (fig. 905).

The **descending colon** [colon descendens] is 25 cm. to 30 cm. in length (less when *in situ*) and extends from the spleen to the pelvic brim (figs. 906, 914). It is more movable than the ascending colon and is also narrower. At its beginning it is usually connected with the diaphragm, on a level with the tenth and eleventh ribs, by a fold of peritoneum, the *phreno-colic ligament* [lig. phrenicocolicum] (or sustentaculum lienis, from the fact that it supports the spleen). The bend between the transverse colon and descending colon is called the left colic or splenic flexure [flexura coli sinistra]. The descending colon is situated in the left hypochondriac, lumbar and iliac regions (fig. 906). Its relations to the peritoneum are the same as obtain with the ascending colon, that is, it is covered in front and on the sides. A mesocolon is met with oftener on this side than on the right, occurring in 36 per cent. of all cases (Treves) (see fig. 902). It is found especially in the lower part of the descending colon, in the iliac fossa. This portion, extending from the iliac crest to the brim (superior aperture) of the pelvis, is sometimes described as a separate segment, the **iliac colon** (Jonnesco).

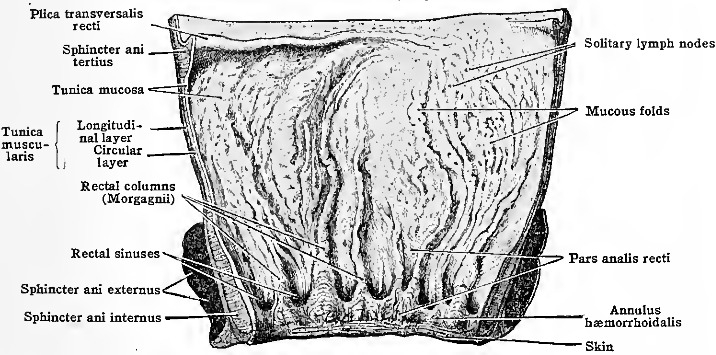
The descending colon is covered *anteriorly* by coils of small intestine; *posteriorly* it is in contact with the lower part of the left kidney, the quadratus lumborum, iliacus and psoas muscles. It terminates by crossing medialward over the psoas muscle and the external iliac vessels to join the sigmoid colon.

The **sigmoid colon** [colon sigmoideum] or pelvic colon, extends from the descending colon to the rectum (figs. 906, 914). It includes what was formerly described as the 'sigmoid flexure' and also the 'first portion' of the rectum. These together form a single loop which cannot conveniently be divided into parts.

The loop, the sigmoid colon, begins at the margin of the psoas, and ends where the sigmoid mesocolon ceases, opposite the second or third sacral vertebra.

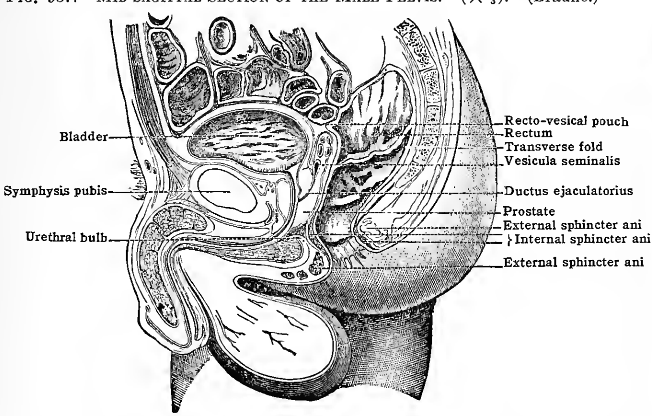
The loop when unfolded describes a figure that may be compared to the capital omega. The average length of this sigmoid colon is about 40 cm. The normal position of the loop is not in the left iliac fossa, but wholly in the pelvis. The most common disposition of it may now be described. The sigmoid (pelvic) colon begins about midway between the lumbo-sacral eminence and the inguinal (Poupart's) ligament. It descends at first along the left pelvic wall, and may at once reach the pelvic floor. It then passes more or less horizontally and transversely across the pelvis from left to right, and commonly comes into contact with the right pelvic wall. At this point it is bent upon itself, and, passing once more toward the left, reaches the middle line and joins the rectum. It will lie, therefore, in more or less direct contact with the bladder (and uterus in the female), and may possibly touch the cæcum. It is very closely related with the coils of small intestine that occupy the pelvis, and by these coils the loop is usually hidden. In about 90 per cent. of cases, the sigmoid colon lies entirely within the true pelvic cavity. In the remainder, it loops upward for a variable distance toward the umbilicus, a position normally found in infancy.

Fig. 936.—Interior of the Rectum. ($\times \frac{3}{5}$.) (From Toldt's Atlas.)



The sigmoid colon is attached to the abdominal and pelvic wall by the sigmoid mesocolon, so that it is quite surrounded by peritoneum. The line of attachment of this mesocolon is as follows: It usually crosses the psoas in a slight curve upward so as to pass over the iliac vessels at or about their bifurcation. The curve ends at a point either just to the medial side of the psoas muscle, or between the psoas and the middle line, or, as is most frequently the case, just over the bifurcation of the vessels. From this point the line of attachment proceeds vertically

Fig. 937.—Mid-sagittal Section of the Male Pelvis. ($\times \frac{1}{3}$). (Braune.)

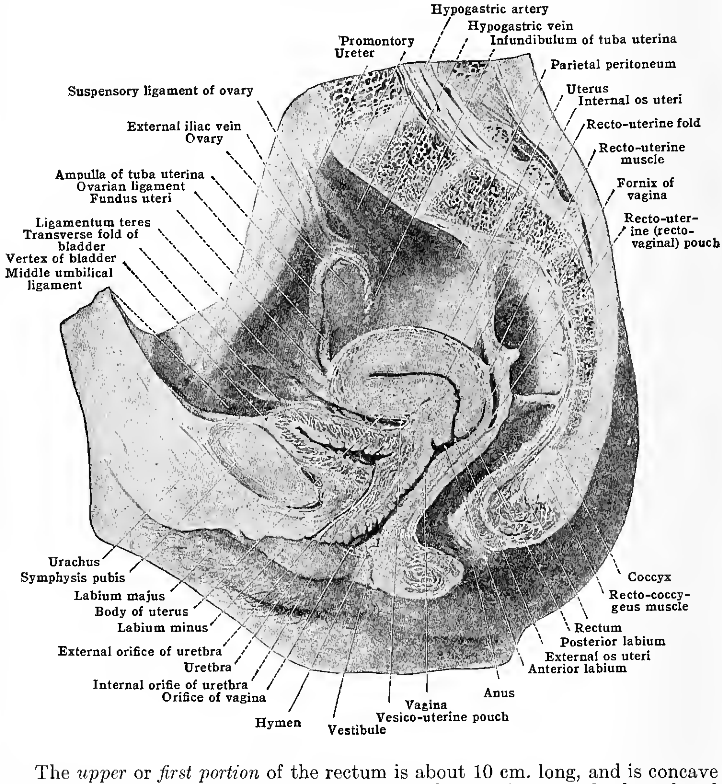


down, taking at first a slight curve to the right. Its course is to the left of the middle line, while its ending will be upon that line, about the second or third sacral vertebra. The sigmoid mesocolon measures from 3 to 8.7 cm. in width—i. e., from the parietes to the bowel,—at the widest point.

When a descending mesocolon exists, it joins that of the sigmoid colon. There is often no mesocolon over the psoas, the gut being adherent to that muscle. In connection with the sigmoid mesocolon is often found a fossa or pouch of peritoneum, known as the *intersigmoid fossa* [recessus intersigmoideus]. This pouch is formed by the incomplete adhesion of the primitive mesocolon to the posterior abdominal wall. It is generally found over the bifurcation of the iliac vessels. The pouch is funnel-shaped, and the opening looks downward and to the left. It varies in depth from 2.5 to 3.7 cm., and is rarely the seat of the sigmoid hernia.

The rectum.—The rectum, according to the BNA nomenclature, is recognised as a division separate from the large intestine. The term rectum is now limited to that portion of the bowel below the mid-sacral region, where the mesocolon ceases. It is divided into two portions: the first extends downward and forward, in front of sacrum and coccyx, to the level of the pelvic floor; the second portion (the anal canal) extends from this point downward and backward to the anus (figs. 937, 938).

Fig. 938.—Mid-sagittal Section of the Female Pelvis. (Spalteholz.)



The *upper* or *first portion* of the rectum is about 10 cm. long, and is concave forward [flexura sacralis] except at the lower end where it curves backward and downward [flexura perinealis] to join the second portion. The lower part of the first portion often presents a dilation [ampulla recti], due to accumulation of fæces. This part is sometimes described as the *infra-peritoneal portion* of the rectum proper.

Anteriorly, the rectum is in contact with coils of ileum and, in the male, with the trigone of the bladder, the vesiculæ seminales, ductus deferentes, and posterior aspect of the prostate (fig. 937). In the female, it is in contact anteriorly with the vagina and the cervix uteri (fig. 938). *Posteriorly,* it is in contact with the sacrum, coccyx and ano-coccygeal body.

In the male, a small band of muscle fibres, the *recto-urethral* muscle, extends from the perineal flexure of the rectum to the membranous urethra.

The *peritoneum* is reflected anteriorly from the rectum to the bladder in the male (recto-vesical pouch) and to fornix of the vagina in the female (recto-vaginal pouch). In the newborn, the peritoneum reaches to the base of the prostate (Symington). On the posterior surface of the gut, there is no peritoneum below a point about 12.5 cm. from the anus. Thus the peritoneum at the upper end of the rectum entirely surrounds the gut. Lower down it covers only the sides and anterior wall, and lower still the anterior wall only, where it is reflected upon the bladder or vagina.

The second portion of the rectum, or **anal canal** [pars analis recti] is from 2.5 cm. to 3.5 cm. in length. From the lower end of the first portion, it turns at right angles downward and backward, passing through the pelvic floor, and ending at the anus. It is entirely below the peritoneum, and is surrounded by the two sphincter muscles (figs. 936, 937).

Anteriorly is the bulb of the urethra and the posterior margin of the urogenital trigone in the male (fig. 937), while in the female it is separated from the vestibule and the lower part of the vagina by the 'perineal body' (fig. 938). *Posteriorly* it is connected with the tip of the coccyx by the ano-coccygeal body. *Laterally* it is in contact with the margins of the levatores ani, which act as an accessory sphincter, and help to support the ampulla recti.

The anus.—The anus is the aperture by which the intestine opens externally. During life it is contracted by the sphincters, so as to give the surrounding skin a wrinkled appearance. Around the lower part of the rectum and anus certain muscles that are connected with its proper function are situated. They are the internal sphincter, the levator ani, and the external sphincter. The levator ani and external sphincter will be found described in the section on Musculature. The *internal sphincter* is a thickening of the circular fibres of the intestine, situated around the second portion or anal canal. It forms a complete muscular ring, 2 to 3 mm. thick, and is composed of non-striated muscle.

The rectum differs from the rest of the colon in having smoother walls and no appendices epiploicæ. At the upper end of the rectum, the tænia libera and tænia omentalis join to form a broad band which spreads out, covering the entire anterior aspect of the rectum. Similarly the tænia mesocolica spreads out upon the posterior aspect. Thus the rectum has a complete longitudinal muscle layer, which, however, is thicker anteriorly and posteriorly than laterally. It sends a bundle of fibres to the coccyx [m. recto-coccygeus]. Below, the longitudinal layer passes between the two sphincters and breaks up into numerous bundles which are interwoven with the external sphincter and levator ani, some of them terminating in the circumanal skin.

Its **mucous membrane** is thicker than that of the rest of the large intestine. Certain folds, chiefly longitudinal in direction, are seen in the lax state of the tube, which disappear when distended, but Houston had described three permanent oblique **transverse folds** [plicæ transversales recti] (fig. 936), containing bundles of non-striated muscle-cells, which project into the lumen of the tube: one is on the right at the level of the reflection of the peritoneum from the rectum; and two are on the left, one above and one below the right fold. That upon the right side is the largest and most constant, and its muscular bundle is sometimes called the *sphincter tertius.* It is located about 7.5 cm. above the anus. These folds, like the corresponding semilunar folds of the colon, when well marked involve the entire wall.

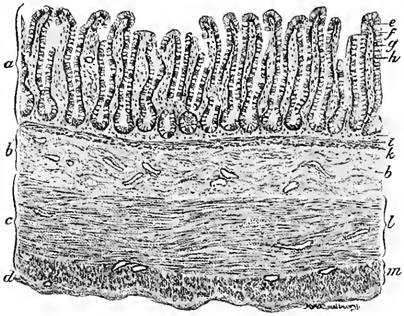
The mucous membrane of the upper portion of the anal canal presents a series of vertical folds known as **rectal columns** [columnæ rectales] (columns of Morgagni), containing bundles of non-striated muscle longitudinally arranged. These columns become more prominent as they extend downward. Just above the anus each two adjacent columns are united by an arch-like fold of mucous membrane, these folds forming what are known as the **anal valves,** while the small fossæ behind them are known as the **rectal sinuses.** The area below the valves and extending to the anus is termed the *annulus hæmorrhoidalis* (fig. 936). This is lined by a modified skin, while the area above the valves forms a transition to the typical mucosa of the rectum.

Minute structure of the large intestine.—In general, the large intestine has the four coats (fig. 939)—mucosa, submucosa, muscularis, and serosa—characteristic of the alimentary canal. The *mucosa* lacks the villi and plicæ circulares characteristic of the small intestine. It contains many solitary lymphatic nodules, but no Peyer's patches. It differs from the stomach in the absence of foveolæ, and in the presence of large numbers of mucous 'goblet cells' found both on the surface and along the numerous crypts of Lieberkuehn (which contain no cells of Paneth). The *submucosa* is much as in the small intestine. The *muscularis* has a continuous inner circular layer, the outer longitudinal fibres being chiefly gathered into the three bands, the teniæ coli, as above mentioned. The serosa is typical, excepting extraperitoneal areas where the epithelium is lacking. The appendices epiploicæ were also mentioned above.

The cæcum and colon present no special features worthy of mention, beyond the typical structure above outlined.

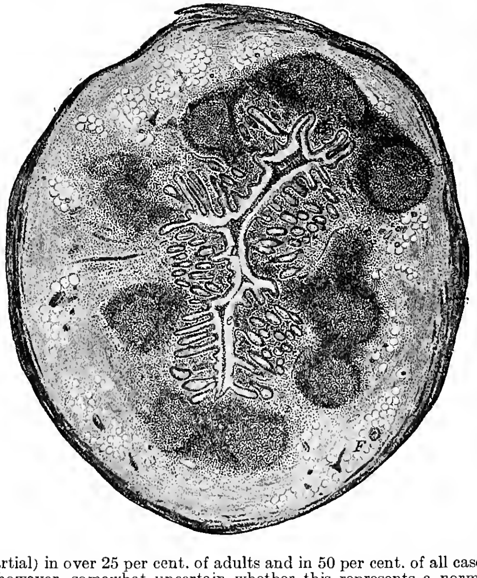
The *vermiform process*, however, differs in several important respects (fig. 940). The walls are relatively thick and the lumen small. The solitary lymph nodules are closely packed or confluent (especially in young people). They occupy the greater part of the submucosa, and somewhat resemble the Peyer's patches of the ileum. They, like all the lymphoid structures

FIG. 939.—CROSS-SECTION OF THE LARGE INTESTINE. *a*, Mucosa. *b*, Submucosa. *c*, Muscularis. *d*, Serosa. (Radasch.)



in general, tend to become atrophied in old age. Fat cells are usually abundant in the submucosa. The *muscularis* presents an inner circular layer and also a thin but complete outer longitudinal layer. The serosa is typical. The lumen shows a progressive tendency to obliteration as age advances (Ribbert). This condition is never found in infancy but occurs

FIG. 940.—TRANSVERSE SECTION OF THE HUMAN VERMIFORM PROCESS. (× 20). (Stöhr and Lewis, from Sobotta.) Note absence of villi and abundance of lymph nodules. *F*, Clusters of fat cells in submucosa. Only the inner part of the circular muscle is shown.



usually only partial) in over 25 per cent. of adults and in 50 per cent. of all cases over 50 years of age. It is, however, somewhat uncertain whether this represents a normal process. In obliteration, the glands and lymphoid nodules disappear, and the entire mucosa is transformed into an axial mass of fibrous connective tissue.

The *rectum* also presents several peculiarities of structure. Attention has already been called to the transverse folds (of Houston) and the rectal columns, sinuses and valves. Just above the valves, the mucosa is transitional, the epithelium being partly stratified, and the crypts of Lieberkuehn few and scattering. Below the valves, the annulus hæmorrhoidalis is lined by a modified skin. Hairs and sebaceous and sweat glands do not appear until just outside the anal orifice. The thickening of the circular muscle to form the internal sphincter, and the somewhat uniform disposition of the longitudinal muscle have already been mentioned, as well as the absence of a serous coat in the lower portions.

Blood-vessels.—The large intestine is supplied with blood by the branches of the superior mesenteric and inferior mesenteric arteries, while it also receives a blood-supply from the internal iliac at the rectum. The vessels form a continuous series of arches from the cæcum, where the vasa intestini tenuis anastomose with the ileo-colic, the first branch of the superior mesenteric given to the large intestine.

The blood-supply of the rectum is from the inferior mesenteric by the superior hæmorrhoidal, from the hypogastric (internal iliac) by the middle hæmorrhoidal, and from the internal pudic by the inferior hæmorrhoidal. The vessels at the lower end of the rectum assume a longitudinal direction, communicating freely near the anus, and less freely above.

The blood of the large intestine is returned into the portal vein by means of the superior mesenteric and inferior mesenteric veins. At the rectum a communication is set up between the systemic and portal system of veins, since some of the blood of that part of the intestine is returned into the hypogastric (internal iliac) veins. In the lower end of the rectum the veins, like the arteries, are arranged longitudinally. This arrangement is called the hæmorrhoidal plexus.

The vermiform process is supplied by a special branch of the ileo-colic artery (fig. 934). This branch, the appendicular artery, crosses behind the terminal portion of the ileum (where pressure may obstruct the circulation) to enter the mesenteriolum. An accessory artery of small size also descends along the medial margin of the colon and cæcum, entering the base of the appendix.

The **nerves** and **lymphatics** of the large intestine differ in no important particular from those of the small intestine, so far as their relations within the intestinal wall are concerned.

The efferent lymphatic vessels in general follow the blood-vessels and pass through corresponding lymph nodes in the various regions (see p. 734). Those of the cæcum and vermiform process pass through the appendicular and ileo-cæcal nodes; those of the colon through mesocolic and mesenteric nodes. Those of the descending and sigmoid colons connect with the inferior mesenteric and lumbar nodes. The superior zone of the rectum is drained by lymphatics passing to the ano-rectal and inferior mesenteric nodes; the middle zone (region of rectal columns) to nodes along the three hæmorrhoidal arteries; the inferior zone (anal integument) chiefly to the superficial inguinal nodes.

Development of the large intestine.—At an early stage in the development of the intestinal canal, when this presents a single primary loop and soon after this loop has turned on its axis, there is observed on the left half of the loop, near its top, an enlargement which marks the beginning of the large intestine. With further growth this enlargement develops a lateral outgrowth on the side opposite to that to which the mesentery is attached, therefore free from the mesentery. A conical projection of the large intestine or colon beyond the place where this is joined to the small intestine is thus formed. This conical projection or pouch of the large intestine, which continues the colon somewhat beyond the insertion of the small intestine, develops into the cæcum and the vermiform process. It does not present, in its further growth, a uniform enlargement. The portion nearest the colon grows in size more rapidly than the terminal portion, this difference in size becoming more apparent as development proceeds, the smaller terminal portion forming the vermiform process. On the return of the intestine to the peritoneal cavity (in embryos of about 40 mm.) the cæcum lies on the right side, immediately below the liver. During the later fœtal months the cæcum gradually descends into the right iliac fossa, and there is thus established an ascending colon. The cæcum may, however, even in the adult, retain its embryonic position on the right side immediately beneath the liver, or may descend farther than usual.

The ascending and descending colons, the sigmoid meso-colon (in part), and the rectum with corresponding portions of the mesorectum, become adherent to the posterior body wall during the fourth and fifth fœtal months. At the same time, the posterior layer of the great omentum becomes fused with the upper (anterior) surface of the transverse meso-colon. The layer of retroperitoneal fascia corresponding to the obliterated mesocolon is shown in fig. 1005. Variations in the process of fusion give rise to numerous peritoneal variations in the adult.

The sigmoid colon is relatively long at birth. On account of the relatively small size of the true pelvic cavity, both sigmoid colon and coils of ileum are usually excluded from it in the fœtus and infant.

In fœtuses of four to six months (length 100 mm. to 240 mm.) transitory villi appear in the mucosa throughout the large intestine, including the vermiform process. They appear in rows, corresponding to longitudinal folds. Their early obliteration is possibly due to distention of the gut by the meconium. The glands bud off like those of the small intestine. Lymphoid nodules are present abundantly in the vermiform process at birth (Johnson). The circular muscular layer begins to appear in the lower part of the large intestine at 23 mm.; the teniæ at 75 to 99 mm. (F. T. Lewis).

Development of the rectum and anus.—The posterior end of the primitive intestine or archenteron, designated the hind-gut, presents a terminal portion which is somewhat dilated and known as the cloaca, into the lateral and ventral portions of which open the Wolffian ducts, and from the ventral portion of which arises the allantois. The ventral portion of the cloaca, which is an entodermal structure, comes in contact with the ectoderm to form the cloacal membrane, and this forms the floor of a slight depression. For a time the cloaca or hind-gut extends for some distance caudal to the cloacal membrane, forming what is known as the post anal gut; this, however, soon disappears. Early in the development of the human embryo when this has attained a length of about 6.5 mm., the fold which separates the cloaca and hind, gut from the allantois deepens, and folds develop from the lateral walls of the cloaca which meet and gradually separate the cloaca into a dorsal portion, which forms the rectum, and a ventral portion which forms the uro-genital sinus. This uro-rectal septum extends in its further growth until the cloacal membrane is reached, separating it into a ventral portion known as the uro-genital membrane, and a dorsal portion known as the anal membrane. The anal membrane ruptures comparatively late in development, establishing thus a communication between the hind-gut (rectum) and the exterior. The mesoderm develops around the lower end of the rectum, so that the ectoderm becomes slightly invaginated and lines the portion of the anal canal below the valves. A want of rupture of the anal membrane constitutes an arrest of development known as atresia of the anus.

Folds of the mucosa representing the rectal columns, valves and sinuses appear in embryos during the third month, and are well developed during the latter half of the fœtal period (Johnson).

Variations.—The large intestine is exceedingly variable in its structure and relations, especially with reference to the peritoneum—so much so that it has been found more convenient to include a consideration of the variations along with the preceding description of the individual parts. The content of fæces (and gas) is as a rule relatively greatest in the cæcum, decreasing in ascending and transverse colons. The descending colon is usually empty, or nearly so, the sigmoid colon and rectum somewhat variable. The rectal ampulla is usually more dilated in women.

Comparative.—The morphology of both small and large intestines will be briefly considered here. As previously mentioned, the primitive form of intestine is a comparatively straight tube extending from stomach to anus, and connected by a primitive mesentery to the mid-dorsal line of the body cavity. There is in many of the lower forms no clear division into small and large intestine, though the rectal region is usually more dilated, and opens into a cloaca. *Diverticula* often occur in the region between large and small intestine. In many fishes, numerous "cæca" occur just below the pylorus, and in others an extensive *spiral valve* projects into the lumen of the intestine. The absorptive and digestive surface of the mucosa is further increased by the formation of various kinds of *folds*, and (beginning in amphibia) of *villi*. *Lymphoid tissue* is typically present in the mucosa, often localized in definite masses. Solitary nodules appear in amphibia, and Peyer's patches in birds. Tubular mucous glands occur in the lower forms, but Brunner's glands and crypts of Lieberkuehn with Paneth cells apparently only in mammals. A *cæcum* is usually present from the reptiles upward (double in birds), and often forms an important organ of digestion. The bile and pancreatic ducts open constantly a short distance below the pylorus. The small intestine is always longer than the large, but there is extreme variation in length among the various species. The four tunics—mucosa, submucosa, muscularis and serosa—are typical for vertebrates, the muscularis consisting of inner circular and outer longitudinal smooth muscle fibres.

Among *mammals*, the divisions of the intestine correspond in general to those found in the human species, but there is exceedingly great variation in the relative development of the various parts. In general, the length, size and complexity of structure is relatively greatest in the *herbivora* (whose food is more difficult of digestion), least in the *carnivora*, and intermediate in the *omnivora*. Even in the same species, the structure of the intestine may be appreciably modified according to habitual diet. The large intestine varies, but is always shorter and wider than the small intestine. In mammals the rectum only is said to be homologous with the large intestine of lower vertebrates. The *cæcum* is rarely absent and is enormously developed in herbivora. It often contains large amounts of lymphoid tissue, which, in pig and ox forms a so-called 'intestinal tonsil.' The *vermiform process* (found typically developed in man and higher anthropoids) apparently represents a retrogressive evolutionary change in the cæcal apex, although this interpretation is denied by some (Berry), who interpret the appendix as a progressive, functional lymphoid organ.

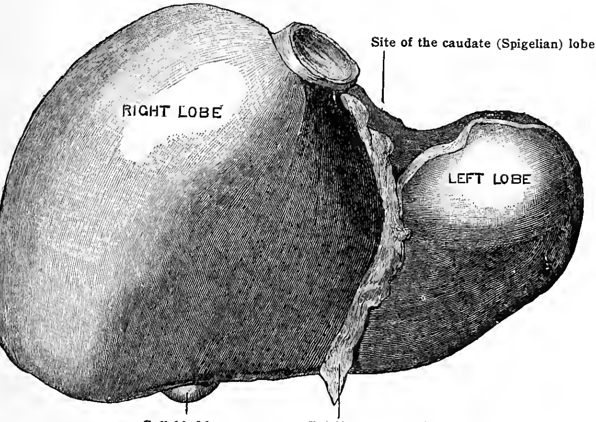
THE LIVER

The **liver** [hepar] is the largest gland in the body. Its secretion, the bile [bilis; fel], is poured into the duodenum through the common bile duct. In addition it has important functions as a 'ductless gland' in connection with the nitrogenous and carbohydrate metabolism. In form it is a variable somewhat irregular mass, roughly comparable to a modified hemisphere occupying the upper right portion of the abdominal cavity (figs. 899, 914). It presents a convex, rounded upper or *parietal* aspect, which is in contact with the diaphragm and adjacent body walls, and a lower, flattened *visceral* surface, in contact with the abdominal viscera. When viewed from the front, it is somewhat triangular in outline, occupying the right hypochondriac, the epigastric and (slightly) the left hypochondriac regions.

Physical characters.—In weight, the liver averages about 1500 gm. ($3\frac{1}{3}$ lbs.), but it is exceedingly variable, commonly ranging from 1000 gm. to 2000 gm. Its *relative* weight is also variable, averaging about 2.5 per cent. of the body in the adult male (somewhat higher in the female). Its *specific gravity* averages 1.056, so that the average weight of 1500 gm. would correspond to a *volume* of 1420 cc. Its *dimensions* are also quite variable. Its greatest *depth* (antero-posterior) averages about 15 cm., and its greatest *height* (vertical) is about the same. Its *width* (horizontal) is about 20 cm., while its greatest *length* (measured obliquely from side to side) averages about 25 cm. The *colour* of the liver is a reddish-brown. It is firm in *consistency*, but friable, so that it is easily ruptured.

Surfaces and borders.—The most general division of the surface of the liver,

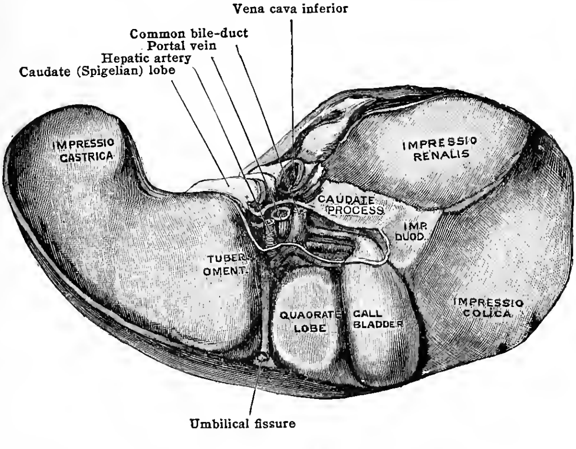
Fig. 941.—Superior Surface of the Liver.



as above stated, is into two—the parietal and the visceral. The parietal surface is again subdivided, usually into two surfaces—posterior and superior.

The **posterior surface** [facies posterior] is triangular (fig. 943). It is wide on the right, where the right lobe is in contact with the diaphragm (corresponding

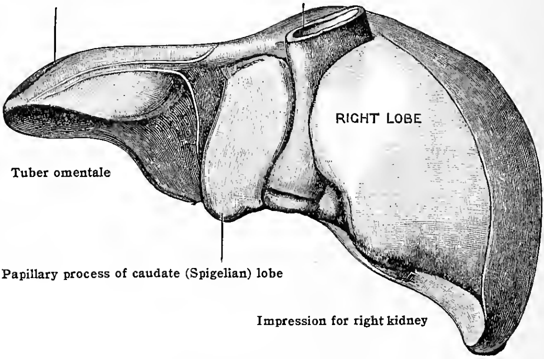
Fig. 942.—Inferior Surface of the Liver.



chiefly to the 'uncovered area' of the coronary ligament), and narrow on the left side, where the posterior margin of the left lobe is likewise attached to the diaphragm. At the lower, left hand corner of the right lobe is a small triangular area of contact with the suprarenal body [impressio suprarenalis]. Near the mid-line is the caudate (Spigelian) lobe, opposite the tenth and eleventh thoracic vertebral bodies, from which it is separated by the diaphragm (chiefly the right crus). On the right of the caudate lobe is the fossa lodging the vena cava (sometimes bridged over), while to the left is the fissure of the ductus venosus, giving attachment to the upper portion of the lesser omentum (relations in cross-section shown in fig. 945).

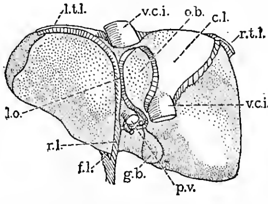
The **superior surface** [facies superior] is in general convex and moulded to the inferior surface of the diaphragm (fig. 941). Tne relations in cross-section of the

Fig. 943.—Posterior Surface of the Liver.



body are shown in fig. 945. It extends downward upon the anterior abdominal wall to a variable extent in the epigastric region, including the entire area of the liver visible from the front (fig. 941). It also presents a broad area extending downward on the right side. Symington accordingly distinguishes three surfaces corresponding to the superior surface above described, viz., right surface, anterior surface and superior surface. The superior surface is related above, through the diaphragm, with the base of the right lung, the pericardium and heart, and (on the extreme left) with the base of the left lung. Where it rests upon the liver, the heart forms a shallow fossa [impressio cardiaca].

Fig. 944.—Diagram Showing Ligaments on the Dorso-inferior Aspect of the Liver. (Lewis and Stöhr.) *c.l.*, Coronary lig. *f.l.* Falciform lig. *g.b.*, Gall bladder. *l.o.*, Lesser omentum. *l.t.l.*, Left triangular lig. *o.b.*, Caudate lobe. *p.v.*, Portal vein. *r.l.*, Lig. teres. *r.t.l.*, Right triangular lig. *v.c.i.*, Vena cava inf.

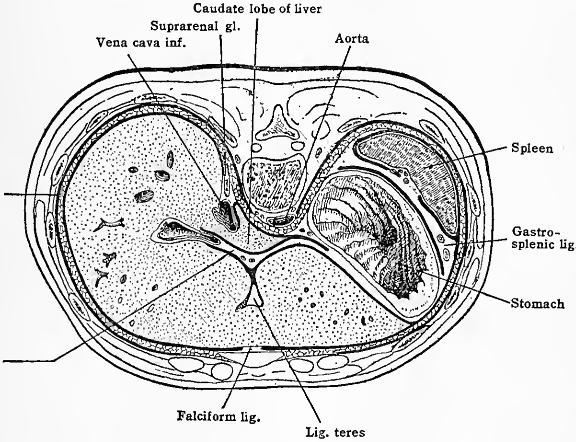


The **inferior** or **visceral surface** [facies inferior] (fig. 942) faces downward and backward. It is irregularly concave, with impressions due to contact with the underlying viscera. It is divided into three lobes, right, left, and quadrate, whose relations will be described later.

Of the **borders,** the *anterior* [margo anterior] is the best marked. It forms the inferior boundary of the triangular anterior view of the liver (figs. 899, 914, 941), and separates the superior from the inferior surface. Slightly to the left of the mid-line, it often presents a slight *umbilical* notch [incisura umbilicalis], where it is crossed by the falciform ligament. The posterior surface is separated from the superior and inferior surfaces by ill-defined *postero-superior* and *postero-inferior* borders.

Surface outline.—The average position of the liver may be outlined upon the anterior surface of the body as follows (fig. 914): Locate one point on the right mid-clavicular (mid-Poupart) line opposite the fifth rib; a second point on the left mid-clavicular line about 2 cm. lower, in the fifth interspace; and a third point about 2 cm. below the costal arch (10th rib) on the right lateral wall. A line slightly concave upward, joining the first and second points defines the uppermost aspect of the lever. A line, strongly convex laterally, joining the first and third points, defines the right side of the liver. Finally, a third line, joining the second and third points, corresponds to the anterior border and defines the lowermost portion of the liver. This line is subject to many individual variations. In general, it is usually slightly convex downward as it crosses the epigastric region. It usually presents a slight umbilical notch, as before mentioned, and frequently a notch for the fundus of the gall-bladder, which is placed near the right mammary (mid-Poupart) line. The lower and right portion of the anterior border of the liver runs somewhat parallel with the infracostal margin. In the upright position, and in livers larger than usual, it extends about 2 cm. below the hypochondrium into the right lateral abdominal (lumbar) region (fig. 914). In the supine position, however, the liver recedes about 2 cm. toward the head. The liver of course participates also in the respiratory movements of the diaphragm.

Fig. 945.—Cross-section of Body at Level of the Eleventh Thoracic Vertebra. (Poirier-Charpy.)



Lobes and fissures.—The superior surface is divided by the falciform ligament into two areas, corresponding to a larger right and a smaller left lobe (fig. 941). On the posterior and inferior surfaces of the liver (figs. 942, 943), an H-shaped arrangement of fossæ and fissures completes the demarcation of lobes. The left upright of the H [fossa sagittalis sinistra] corresponds to the prolongation of the line of attachment of the falciform ligament. It is made up of the umbilical fissure [fossa venæ umbilicalis], containing the round ligament, on the inferior surface; and of the *fossa ductus venosi*, containing the ligamentum venosum (obliterated ductus venosus) and the upper part of the lesser omentum, on the posterior surface of the liver. This left sagittal fossa separates the left lobe of the liver from the right lobe (in the wider sense of the term). The right lobe is further subdivided by the right upright and cross-bar of the H. The right upright [fossæ sagittales dextræ] is made up of the broad *fossa for the gall-bladder* [fossa vesicæ felleæ] on the inferior surface, and the broad *fossa venæ cavæ* on the posterior surface (fig. 943. These two fossæ are not continuous, but are separated by a narrow strip of liver, the caudate process of the caudate lobe (fig. 942). The cross-bar of the H is formed by the transverse or *portal fissure* [porta hepatis], which encloses the root structures of the liver, within the lower part of the lesser omentum (fig. 942). The area anterior to the cross-bar of the H corresponds to the quadrate lobe of the inferior surface; that posterior to the cross-bar to the caudate lobe of the posterior surface; while the remainder of the liver, to the right of the H, is the right lobe (in the narrower sense).

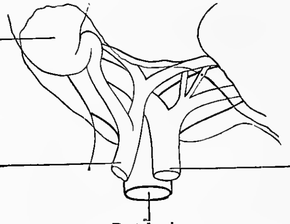
The **right lobe** [lobus hepatis dexter] makes up the greater part of the liver. Its relations on the superior and posterior surfaces have already been mentioned. On the inferior or visceral surface (fig. 942), there appears posteriorly a large concavity [impressio renalis] for the right kidney; medially a faint impression [impressio duodenalis] for the descending duodenum; and antero-inferiorly a variable area [impressio colica] of contact with the right (hepatic) flexure of the colon. The caudate process joins the right with the caudate lobe.

The **left lobe** [lobus hepatis sinister] lies to the left of the left sagittal fissure and the falciform ligament. It is flattened but variable in form and size, and makes only about one-fifth of the entire liver. In children and especially in early fœtal life, it is relatively much larger. At the left extremity, there is usually found in the adult liver a variable fibrous band [appendix fibrosa hepatis] representing the atrophied remnant of the more extensive gland in earlier life. In this fibrous appendix (and in other parts of the liver) the bile ducts of the atrophied liver substance persist as *vasa aberrantia hepatis.*

The left lobe is related *superiorly*, through the diaphragm, with the heart and the base of the left lung. *Inferiorly* (fig. 942) it presents a large concavity [impressio gastrica] which is in contact with the anterior surface of the stomach. Above and behind the gastric impression is the rounded *tuber omentale* which is placed above the lesser curvature of the stomach and related, through the lesser omentum, with a corresponding tuberosity on the pancreas. To the left of the tuber omentale, and near the posterior aspect of the liver, is a small inconspicuous groove [impressio œsophagea] for the abdominal part of the œsophagus.

The **quadrate lobe** [lobus quadratus] lies, as before mentioned, on the inferior surface of the liver (fig. 942) in the anterior or inferior area of the H. It is in contact with the pylorus and the first part of the duodenum.

Fig. 946.—Relation of Structures at and Below the Transverse or Portal Fissure. Anteior view. (Thane.)



The **caudate** or **Spigelian lobe** [lobus caudatus; Spigeli] was described on the posterior surface of the liver (fig. 943). Inferiorly, the caudate lobe, behind the portal fissure, is divided by a notch into two processes. The left or *papillary process* [processus papillaris] is short and rounded, and lies opposite the tuber omentale. In the fœtus it is relatively much larger and is in contact with the pancreas. The right or *caudate process* [processus caudatus] is of variable size, and joins the caudate with the right lobe of the liver. It is usually small and inconspicuous. In the fœtus, however, it is relatively much larger, and extends downward to a variable extent behind the duodenum and head of the pancreas. In the adult, it forms the upper boundary of the epiploic foramen (of Winslow).

Peritoneal relations.—The liver in the adult is almost entirely surrounded by peritoneum. Although it develops together with the diaphragm in the common septum transversum (as explained previously, see figs. 951,952), the peritoneum soon extends in between liver and diaphragm, so that they remain in immediate contact only in the so-called 'uncovered area.' This is an irregular area on the posterior surface of the liver (chiefly on the right lobe), the margins of which correspond to the coronary ligament (figs. 905, 944). The posterior surface of the liver is therefore chiefly retroperitoneal, excepting the caudate (Spigelian) lobe, which is in contact with the recessus superior of the bursa omentalis (fig. 905). The superior and inferior surfaces of the liver are entirely covered with peritoneum, excepting the lines of attachment of the various peritoneal ligaments, and the fossa for the gall-bladder, which is usually directly in contact with the gall bladder with no intervening peritoneum.

Ligaments.—The liver is attached by five peritoneal ligaments—coronary, right and left triangular (lateral) and falciform ligaments and lesser omentum—and two accessory ligaments—teres and venosum.

The **coronary** ligament [lig. coronarium hepatis], as before mentioned, corresponds to the reflections of peritoneum from the liver to the diaphragm at the margins of the 'uncovered area' (fig. 944) on the posterior surface of the liver.

Within this uncovered area the hepatic veins join the inferior vena cava. The coronary ligament, though somewhat irregular and variable in form, is elongated laterally and roughly quadrangular. At the four angles, the peritoneal layers come together and are prolonged into four ligaments—right and left triangular (lateral) and falciform ligaments and lesser omentum. There is often also a special prolongation of the coronary ligament downward upon the right kidney, forming the hepato-renal ligament [lig. hepatorenale]. This lies to the right of the foramen epiploicum.

The **right triangular** (or lateral) ligament [lig. triangulare dextrum] is a short but variable prolongation of the coronary ligament to the right and downward (figs. 905, 944). It connects the posterior surface of the right lobe of the liver with the corresponding portion of the diaphragm.

The **left triangular** (lateral) ligament [lig. triangulare sinistrum] is a longer, narrower prolongation of the coronary ligament to the left (figs. 905. 944). It connects the posterior aspect of the left lobe of the liver with the corresponding portion of the diaphragm.

The **falciform** ligament [lig. falciforme hepatis] is a double layer of peritoneum representing (as before mentioned) the ventral portion of the primitive ventral mesogastrium.

Its upper end is continuous posteriorly with the coronary ligament. It passes forward and downward over the superior surface of the liver. From its line of attachment to the liver (between right and left lobes) it passes forward and slightly to the left to the attachment on the anterior body wall. This attachment extends downward slightly to the right of the mid-line to the umbilicus. The lower margin of the falciform ligament is free, and encloses the round ligament.

The **round ligament** [lig. teres hepatis] is a fibrous cord representing the obliterated fœtal left umbilical vein. It extends upward from the umbilicus enclosed in the lower margin of the falciform ligament.

At the anterior margin of the liver it passes backward on the inferior surface, enclosed in a slight peritoneal fold at the bottom of the fossa venæ umbilicalis (sometimes bridged over by liver tissue). It ends by joining the left branch of the portal vein.

The **ligamentum venosum** [lig. venosum; Arantii] similarly represents the obliterated fœtal ductus venosus. It is a fibrous cord lying in the fossa ductus venosi, and extends from the left branch of the portal vein upward to the left hepatic vein near its opening into the vena cava. The ligamentum venosum lies within the hepatic attachment of the lesser omentum.

The **lesser omentum** [omentum minus] has already been discussed in connection with the peritoneum. It represents the dorsal part of the primitive ventral mesogastrium, extending from the stomach to the liver. It includes two parts, as shown in fig. 906.

The upper and larger part forms the *gastro-hepatic* ligament [lig. hepato-gastricum], connecting the liver (fossa ductus venosi) with the lesser curvature of the stomach. The upper part of this ligament is somewhat thicker, the lower part thinner and more transparent. The relations of the lesser omentum in cross-section of the body are shown in fig. 903. The lower and right portion of the lesser omentum extends beyond the pylorus and connects the portal fissure with the duodenum, forming the *hepato-duodenal* ligament [lig. hepatoduodenale] (fig. 905). Its right margin forms the anterior boundary of the epiploic foramen (of Winslow). Between its layers are located the root structures of the liver, as follows: hepatic artery to the left, common bile duct to the right, portal vein behind and between. A special prolongation of the hepato-duodenal ligament frequently extends downward to the transverse colon, forming the *hepato-colic* ligament [lig. hepatocolicum].

Fixation of the liver.—The liver is to a certain extent fixed in place by means of its various ligaments, and especially through the attachment of the hepatic veins to the inferior vena cava. On account of the close apposition of the liver to the diaphragm, the atmospheric pressure also helps in its support. Finally, the support of the liver, as well as of the abdominal viscera in general, is dependent to a considerable extent upon the tonic contraction of the abdominal muscles, which exerts a constant pressure upon the abdominal contents.

Blood-vessels.—The liver receives its *arterial* supply of blood from the hepatic artery, a branch of the cœliac, which passes up between the two layers of the lesser omentum, and dividing into two branches, one for each lobe, enters the liver at the portal fissure. The right branch gives off a branch to the gall-bladder. The liver receives a much larger supply of blood from the *portal vein,* which conveys to the liver blood from the stomach, intestines, pancreas, and spleen. It enters the portal fissure, and there divides into two branches. Below this fissure the hepatic artery lies to the left, the bile-duct to the right, and the portal vein behind and between the two (fig. 946). These three structures ascend to the liver between the layers of the lesser omentum in front of the epiploic foramen. At the actual fissure the order of the three structures from before backward is—duct, artery, vein.

The *hepatic veins*, by which the blood of the liver passes into the inferior vena cava, open usually by two large and several small openings into that vessel on the posterior surface of the gland at the bottom of the fossa venæ cavæ.

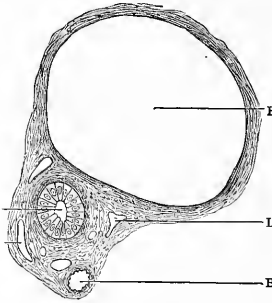
Lymphatics.—The lymphatics are divided into a deep and a superficial set. The *deep set* runs with the branches of the portal vein, artery, and duct through the liver, leaving at the portal fissure, where they join the vessels of the superficial set. The efferent deep vessels after leaving the portal fissure pass down in the lesser omentum in front of the portal vein, through the chain of hepatic lymphatic nodes, and ultimately end in a group of nodes at the upper border of the neck of the pancreas, in which the pyloric lymphatics also terminate.

The *superficial set* begins in the subperitoneal tissue. Those of the *upper surface* consist:—(1) Of vessels which pass up, principally, in the falciform ligament and right and left triangular ligaments, through the diaphragm, and so into the anterior mediastinal nodes, and finally into the right lymphatic duct. Some lymphatics of the right triangular ligament pass to the posterior mediastinal lymph-nodes and into the thoracic duct. (2) Of a set passing downward over the anterior border of the liver to the hepatic nodes in the portal fissure, and over the posterior surface to reach the superior gastric and cœliac nodes. On the lower surface, the lymphatics to the right of the gall-bladder enter the lumbar nodes. Those around the gall-bladder enter the hepatic nodes of the lesser omentum. Those to the left of the gall-bladder enter the superior gastric nodes.

Nerves.—The nerves of the liver are derived from the vagi (those from the left vagus entering from the stomach through the lesser omentum), and from the cœliac plexus of the sympathetic (including right vagus branches) through a plexus accompanying the hepatic artery. The terminations, so far as known, are chiefly to the walls of the vessels and of the bile ducts.

Structure of the liver.—The liver is, for the greater part, covered by peritoneum, beneath which is found the fibro-elastic layer known as Glisson's capsule. At the portal fissure, Glisson's capsule passes into the substance of the liver, accompanying the portal vessels, the branches of the hepatic artery, and the bile-ducts. The liver substance is composed of vascular units measuring from 1 to 2 mm., and known as liver lobules. These are in part (man) separated by

Fig. 947.—Section of a Portal Canal. (Quain.)



a small amount of interlobular connective tissue, which is a continuation of Glisson's capsule. In this interlobular connective tissue are found the terminal branches of the portal vessels; the hepatic artery, and the bile-ducts (figs. 947, 948). The branches of the portal vessels which encircle the liver lobules are known as the interlobular veins. From these are given off hepatic capillaries, which anastomose freely, but have in general a direction toward the centre of the lobule, and unite to form the central or intralobular veins, which in turn unite to form the sublobular veins, and these the hepatic veins. The intralobular branches of the hepatic arteries form capillaries which unite with the capillaries of the intralobular portal veins.

The liver is a modified compound tubular gland. The liver-cells are arranged in anastomosing cords and columns occupying the spaces formed by the hepatic capillaries. The bile-ducts have their origin in so-called bile-capillaries [ductus biliferi], situated in the columns of liver-cells; they anastomose freely and pass to the periphery of the lobules to form the primary divisions of the bile-ducts, and these unite to form the larger bile-ducts. The branches of the portal vessel are accompanied in their course through the liver by the branches of the hepatic artery and the bile-ducts, surrounded by extensions of Glisson's capsule forming the so-called 'portal canals' (fig. 947). The branches of the hepatic vein are solitary, their walls are thin and closely adherent to the liver substance, whence they remain wide open on sectioning the liver.

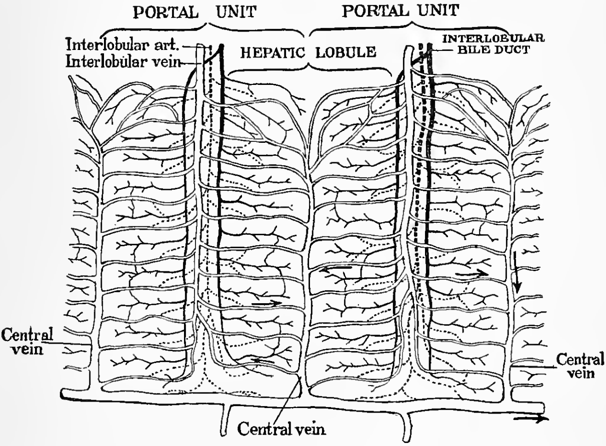
While it is customary to describe thus the liver lobules, it would be more logical to consider as the real lobules what Mall has described as the 'portal units.' Each portal unit includes the territory supplied by one interlobular branch of the portal vein, and drained by the accompanying bile-duct. The relations of the ordinary lobules and the portal units are evident in fig. 948. The portal unit corresponds more nearly to the lobule of other glands, where the duct is in the centre of the lobule.

Bile passages.—The bile passages, which transmit the bile from the liver to the duodenum, include the gall-bladder, the cystic duct, the hepatic ducts, and the common bile duct.

The **gall-bladder** [vesica fellea], which retains the bile, is situated between the right and quadrate lobes on the lower surface of the liver. It is pear-shaped, and when full, is usually seen projecting beyond the anterior border of the liver, coming in contact with the abdominal wall opposite the ninth costal cartilage at the lateral margin of the right rectus muscle (fig. 914). It extends back as far as the portal fissure.

It measures in length, from before backward, 7 to 10 cm. It is 2.5 to 3.5 cm. across at the widest part, and will hold about 35 cc. ($1\frac{1}{4}$ oz.). The broad end of the sac is directed forward, downward, and to the right, and is called the *fundus*. The narrow end, or *neck* [collum vesicæ felleæ], which is curved first to the right, then to the left, lies within the gastro-duodenal ligament at the portal fissure. The intervening part is called the *body* [corpus vesicæ felleæ].

Fig. 948.—Diagram of the Portal Unit and Vascular Relations of the Hepatic Lobule. (After Szymonowicz.)



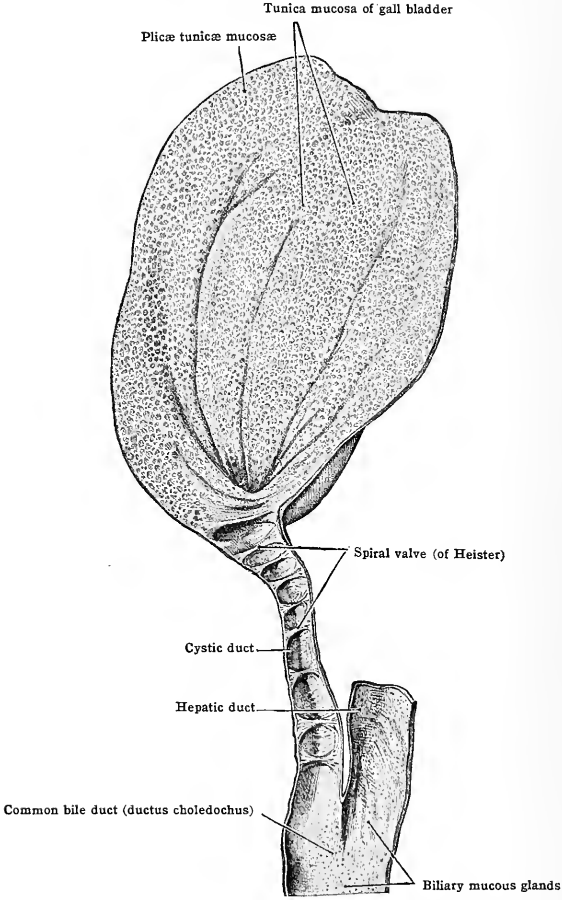
Its *upper surface* is in contact with the liver, lying in the fossa of the gall-bladder. It is attached to the liver by connective tissue. The lower surface is covered by peritoneum, which passes over its sides and inferior surface, though occasionally it entirely surrounds the gall-bladder, forming a sort of mesentery attaching to the liver. The *lower surface* comes into contact with the first part of the duodenum and the transverse colon, and occasionally with the pyloric end of the stomach or small intestine, which *post mortem* are often found stained with bile.

The neck of the gall-bladder opens into the *cystic duct* [ductus cysticus]. This is a tube about 3.5 cm. long and 3 mm. wide, which unites with the hepatic duct to form the ductus choledochus; it is directed backward and to the left as it runs in the gastro-hepatic ligament, the common hepatic artery being to the left and the right branch of the artery and portal vein behind. It joins the hepatic duct at an acute angle, and is kept patent by a spiral valve [valvula spiralis; Heisteri], formed by its mucous coat (fig. 949).

The *hepatic duct* [ductus hepaticus] begins with a branch from each lobe, right and left (that from the left receiving also the ducts from the caudate lobe), in the portal fissure, and is directed downward and to the right within the portal fissure and the hepato-duodenal ligament, the right branch of the hepatic artery being behind and the left branch to the left. It is from 3 to 5 cm. long; its diameter is about 4 mm. Uniting with the cystic duct, it forms the *common bile-duct* [ductus choledochus].

The **ductus choledochus** or **common bile-duct** is about 7.5 cm. in length and 6 mm. in width. It passes down between the layers of the lesser omentum, in front of the portal vein, and to the right of the hepatic artery (fig. 946); it then passes behind the first part of the duodenum, then between the second part and the head of the pancreas, being almost completely embedded in the substance of the pancreas, and ends a little below the middle of the descending duodenum by opening into that part of the intestine on its left side and somewhat behind (figs. 921,

Fig. 949.—Interior of the Gall Bladder and Ducts. (From Toldt's Atlas.)

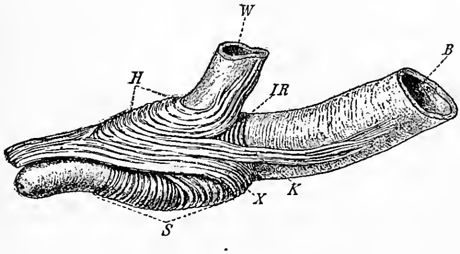


922, 957). It pierces the intestinal wall very obliquely, running between the muscular layers for a distance of about 1 to 2 cm. There is a slight constriction at its termination. The pancreatic duct is generally united with the ductus choledochus just before its termination, and there is a slight papilla at their place of opening on the mucous surface of the duodenum. This papilla is about 8 or 10 cm. from the pylorus. After the pancreatic duct has entered the bile-duct there is (in about half the cases) a dilatation of the common tube called the **ampulla of Vater.**

In its oblique course through the duodenal wall, the common bile duct is accompanied by the pancreatic duct, the two together usually causing the plica longitudinalis duodeni (fig. 922). Circular muscle fibres join with bundles of longitudinal fibres at the lower part of the ducts and form a sphincter around each (fig. 950). Contraction of the sphincter probably closes the orifice of the common bile duct, so that (except during digestion) the bile is backed up into the gall-bladder.

Structure of the gall-bladder.—The wall of the gall-bladder is made up of three coats—mucosa, fibro-muscular and serosa.

Fig. 950.—Macerated Duodenal Portion of the Common Bile Duct, Showing Musculature. *B*, Common bile duct. *W*, Pancreatic duct (of Wirsung). *S*, *IR*, Sphincter fibres of bile duct. *H*, Fibres of pancreatic duct. (Hendrickson.)



1. The *mucosa* is raised into folds bounding polygonal spaces, giving the interior a honeycomb appearance. It is lined with columnar epithelium, and contains a few tubular mucous glands and lymph-nodules, and is limited externally by a poorly developed muscularis mucosæ. At the neck the mucous membrane forms valve-like folds which project into the interior. This layer contains an anastomosis of blood-vessels, the capillaries being most numerous in the folds of the mucosa, and a fine plexus of lymphatics.

2. The *fibro-muscular coat* consists of interlacing bundles of non-striated muscle and fibrous tissue not definitely arranged, the muscular bundles running longitudinally and obliquely This layer contains the principal blood-vessels and lymphatics, and also a nerve plexus.

3. The *serosa* being formed by the peritoneum, is only found on the lower surface and part of the sides.

The *ducts* consist of a fibro-muscular and a mucous layer. In the fibro-muscular layer are non-striated muscle-cells which are chiefly circular, together with white fibrous tissue and elastic fibres. The mucous layer is lined with columnar epithelium, and has many mucous glands. In the cystic duct the mucous membrane is raised into folds, which are crescentic in form, and directed so obliquely as to seem to surround the lumen of the tube in a spiral manner.

The development of the liver.—The relations which the liver bears to the diaphragm, to its vessels and more especially the veins, and to its so-called ligaments, may be understood by a reference to its development (figs. 951, 952). In discussing the development of the peritoneum and the mesenteries it was shown that the liver has its origin in a bud of entoderm, which grows into the transverse septum in the region where this is attached to the ventral mesoderm of the developing intestine; and that, with further development, the transverse septum differentiates into an upper thinner portion, inclosing the Cuvierian ducts, and destined to form the diaphragm, and a lower thicker portion in which the liver develops. Shortly after the formation of the entodermal bud which forms the liver this mass of epithelium becomes penetrated by outgrowths from the omphalo-mesenteric veins, reducing the epithelial mass to anastomosing trabeculæ separated by blood-spaces forming a sinusoidal circulation. The definite hepatic lobules are not differentiated until after birth. The process of the development of the lobules is very complicated, the vascular arrangement being shifted repeatedly (Mall).

The liver rapidly enlarges, filling the upper portion of the abdominal cavity, and extending along its ventral wall to the region of the umbilicus. During the enlargement it in a measure outgrows the transverse septum, and there are developed grooves which result in an infolding of the peritoneum covering the transverse septum, and which in part separate the developing liver from that part of the septum destined to form the diaphragm, and also from the ventral abdominal wall. These grooves appear at the sides and also ventral to the liver, but do not completely separate the liver from the diaphragm, nor do they meet in the median line. A portion of the liver, therefore, remains uncovered by peritoneum, and remains attached to the diaphragm; this area may be known as the uncovered or phrenic area of the liver. Around this area the peritoneum of the liver is reflected on to the diaphragm, forming the coronary ligament, with right and left extensions, designated as the right and left triangular ligaments. Owing to the fact that the grooves which develop on the sides of the liver do not meet in the median line, there persists a fold of peritoneum which attaches the liver to the ventral abdominal

Fig. 952.—Diagram (A): A Sagittal Section of an Embryo showing the Liver enclosed within the Septum Transversum; (B) A Frontal Section of the same; (C) Frontal Section of a Later Stage when the Liver has separated from the Diaphragm.

wall; this forms the falciform ligament, which divides the superior surface of the liver into a right and a left lobe. The region of the attachment of the ventral mesentery (mesogastrium) into which grows the entodermal liver bud, forms the lesser omentum. The developing liver early comes into intimate relation with the omphalo-mesenteric veins, and a little later the umbilical veins. The developmental history of these veins and their relation to the developing liver is discussed elsewhere (see Development of the Portal Vein and Inferior Vena Cava, p. 694). After birth the left umbilical vein forms the hepatic ligamentum teres, situated in the free edge of the falciform ligament. The ductus venosus likewise atrophies to form the ligamentum venosum.

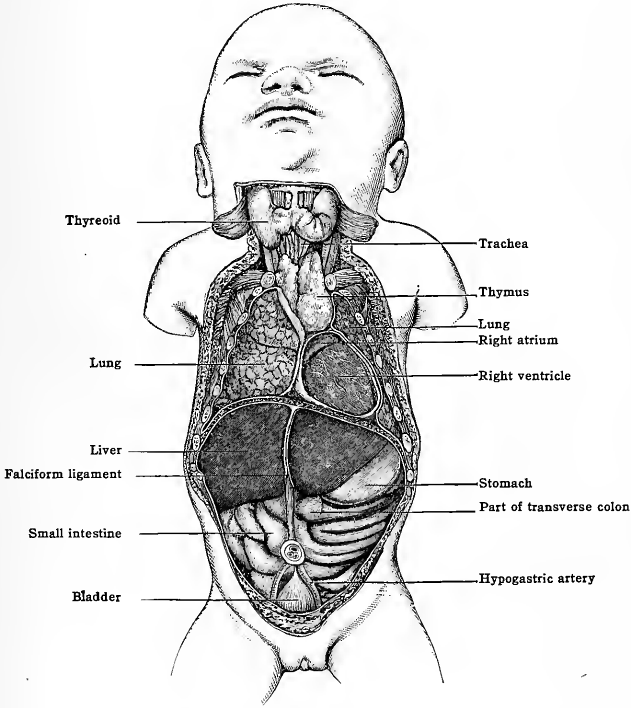
The gall-bladder has its origin in a groove lined by entoderm, which appears on the ventral surface of the primitive intestine or archenteron, between the stomach and the yolk-vesicle. From the cephalic end of this groove grows out the bud destined to form the liver; the caudal end of the groove becomes gradually separated from the developing intestine to form a pouch, lined by entoderm, which forms the beginning of the gall-bladder. With further growth the attachment to the intestine of both the liver and the gall-bladder becomes narrowed to form the ductus choledochus.

During development, the liver undergoes marked changes in form and relative size. It grows with great rapidity in the embryo, its maximum relative size reaching 7 to 10 per cent. of the entire body about the third prenatal month. At this time, the liver is globular in form, the visceral surface very small, and the left lobe more nearly approaching the right in size. During the later fœtal months (fig. 953) and at birth, the liver forms about 5 per cent. of the whole body. It still remains relatively large in infancy, but decreases to about 2.5 per cent. in the adult. From the beginning, the relative weight of the liver averages slightly higher in the female.

Variations of the liver and bile passages.—Many variations of the liver have already been mentioned. In *size*, both relative and absolute, it is subject to marked individual variations, as well as according to age and sex (previously described). In *form*, the liver is also quite variable. There are two extreme types: (1) in which the liver is very wide, extending far over into the left hypochondrium, but relatively flattened from above downward; and (2) in which it extends but slightly to the left, being somewhat flattened from side to side, and elongated vertically. This type may occur as a result of tight lacing, in which the liver is frequently deformed. The part projecting below the right costal margin may form the so-called 'Riedel's lobe.' All intermediate forms between these two types occur. Its *position and relations* will also vary necessarily according to differences in size and shape. For example, in the wide type and also in enlarged livers, the left lobe may extend over upon the spleen, a relation which is constant during prenatal life.

There may be *supernumerary fissures*, dividing the liver into additional lobes, as many as 16 having been described in an extreme case (Moser). These extra fissures often correspond to fissures which are normal in other mammals. There may also be *accessory lobes*, usually small, and connected with the main gland by stalks. Any one of the normal lobes may be *atrophied* or absent. There may also be *abnormal grooves* on the parietal surface of the liver. Of these, there are two varieties: (1) *costal* grooves, due to impressions of the overlying ribs and costal cartilages; and (2) *diaphragmatic* grooves, due to wrinkles in the diaphragm. These

Fig. 953.—The Viscera of the Fœtus. (Rüdinger.)



grooves most frequently occur in females, as a result of tight lacing. The *appendix fibrosa* has already been mentioned. There are numerous variation in the *vascular* arrangements, as well as in the *peritoneal* relations (particularly in connection with the coronary ligament).

The *bile passages* are even more variable than the liver proper. The *gall-bladder* is variable in *size* and capacity (25 cc. to 50 cc. or more), as well as in its *position* and *relations*. The fundus projects to a variable extent beyond the anterior margin of the liver so as to come into contact with the abdominal wall in a little more than half the cases, but is often retracted. The *fossa* of the gall-bladder is of variable depth, rarely so deep that it reaches the superior surface of the liver. The peritoneum usually covers only the sides and inferior surface of the gall-bladder, but occasionally surrounds it entirely, forming a short 'mesentery.' In rare cases the gall-bladder is *bifid* or *double*, and is occasionally *absent*. There are numerous variations in the *bile-ducts*. Rarely the hepatic ducts may communicate directly with the gall-bladder. The point at which hepatic and cystic ducts unite is variable, which affects the relative lengths of these and the ductus choledochus. The latter may open into the duodenum separately, instead of with the pancreatic duct.

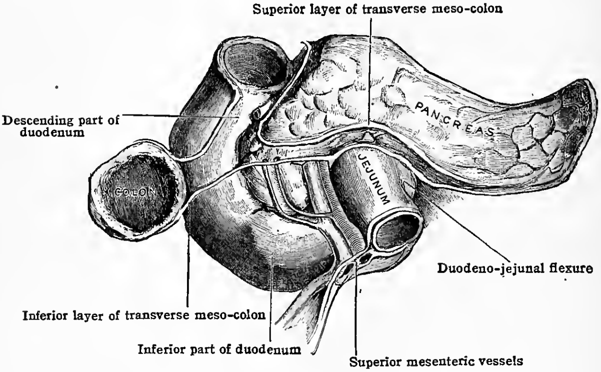
Comparative.—The liver arises in all vertebrates as an outgrowth of the entodermic epithelium of the intestine just beyond the stomach. In amphioxus it remains a simple saccular diverticulum, but in all higher forms becomes a compound tubular gland. The tubular character becomes masked, however (in amniota, and especially in mammals), by the abundant anastomosis between the tubules, forming what is called a 'solid' gland. The relations with the portal venous system are constant. The liver frequently stores large quantities of fat, and may even undergo a complete fatty metamorphosis (lamprey). The colour of the liver is usually reddish-brown, but may be yellow, purple, green or even vermillion (due to bile pigments). In *size*, the liver is variable, but is usually relatively larger in anamniota. Among mammals, there is great variation according to diet, the liver being relatively larger in carnivora, smaller in herbivora, and intermediate in omnivora (including man). It is also relatively larger in *small* animals (including young and fœtal stages), probably on account of their more intense metabolism. There are typically two lobes, right and left, in the vertebrate liver. These are frequently subdivided, however, especially in mammals, which often present numerous lobes.

The gall-bladder is typically present, as in man, but varies in form, size and position. It may be completely buried in the liver. In some species it is absent, in which case the hepatic ducts open directly into the duodenum by one or more apertures. The hepatic and cystic ducts typically unite to form a common bile-duct, as in man, but there are numerous variations in the detailed arrangement of the ducts.

THE PANCREAS

The **pancreas** (figs. 922, 954, 955, 956) is an elongated gland extending transversely across the posterior abdominal wall behind the stomach from the duodenum to the spleen. Through the pancreatic duct, opening into the descending duodenum, flows its secretion [succus pancreaticus], which is of importance in digestion. The pancreas also has a very important internal secretion.

Fig. 954.—The Duodenum and Pancreas, Anterior View.



The pancreas is greyish-pink in colour; average length (*in situ*), 12 cm. to 15 cm.; average weight about 80 gm. (extremes 60 gm. to 100 gm. or more); specific gravity, 1.047, which is about the same as that of the salivary glands.

In *position*, the pancreas lies in the epigastric and left hypochondriac regions. In *form*, it somewhat resembles a pistol, with the handle placed to the right and the barrel to the left. The pancreas is accordingly divided into a *head*, lying within the duodenal loop; a *body*, extending to the left; and a *tail*, or splenic extremity.

The **head** [caput pancreatis] is a discoidal mass somewhat elongated vertically and flattened dorso-ventrally. It forms the enlarged right extremity of the pancreas and lies within the concavity of the duodenum (figs. 922, 954, 955). Its *relations* are as follows (figs. 954, 955, 956): Its *posterior* surface is placed opposite the second and third lumbar vertebræ, and is in contact with the aorta, the vena cava, the renal veins and right renal artery. The common bile-duct is also partly embedded in this surface. Its *anterior* surface is crossed by the transverse colon, above which is the pyloric extremity of the stomach, and below which are coils of

(Addison.)

small intestine. Upon this surface are also the pancreatico-duodenal and (in part) the superior mesenteric vessels. The *margin* of the head of the pancreas is **C**-shaped, corresponding to the inner aspect of the duodenal loop, with which it is closely related. *Superiorly* the margin is in contact with the pylorus and first part of the duodenum; *on the right,* with the descending duodenum and the terminal portion of the common bile duct; *inferiorly,* with the horizontal, and *on the left,* with the terminal ascending portion of the duodenum.

The lower and left portion of the head of the pancreas is hooked around behind the superior mesenteric vessels, forming the **processus uncinatus** or pancreas of Winslow (fig. 922). A groove, the *pancreatic notch* [incisura pancreatis], is thus formed for the vessels. The morphology of this process is explained later under development (fig. 958).

In the adult condition, the head of the pancreas is largely *retroperitoneal.* The only portions covered by peritoneum are (1) a small area above the attachment of the colon, and in relation with a pocket-like recess of the bursa omentalis, and (2) a small area below the transverse colon, which is in relation with coils of small intestine. The mesentery of the small intestine begins where the superior mesenteric vessels pass downward from in front of the processus uncinatus.

The junction of the upper and left aspect of the head with the body of the pancreas is called the *neck.* This is a somewhat constricted portion grooved *posteriorly* by the superior mesenteric vessels, the vein here joining with the splenic to form the portal vein (fig. 955). *Anterior* to the neck is the pyloric portion of the stomach. The upper portion of the neck (together with a variable area on the left end of the body) projects above the lesser curvature of the stomach. This projection [tuber omentale] is related, through the lesser omentum, with a similar tuberosity on the left lobe of the liver. The anterior aspect of the neck is covered with peritoneum of the bursa omentalis (lesser sac), and is continuous with the anterior surface of the body of the pancreas (fig. 922).

The **body** [corpus pancreatis] is the triangularly prismatic portion of the pancreas extending from the neck on the right to the tail on the left. Its *direction* is transversely to the left and (usually) somewhat upward. It is therefore usually placed at a somewhat higher level than the head, opposite the first lumbar vertebra. It presents three surfaces—anterior, posterior, and inferior—and three borders—superior, anterior, and posterior.

Of the **surfaces,** the **anterior** [facies anterior] faces forward and somewhat upward. It is covered with the peritoneum of the posterior wall of the bursa omentalis (lesser sac), and forms a slightly concave area which is in contact with the posterior surface of the stomach (figs. 904, 906). The **posterior** surface [f. posterior] of the body of the pancreas is flattened and retroperitoneal. From right to left it crosses the anterior aspect of aorta, left suprarenal body and left kidney. The splenic vessels also run along the posterior surface, the artery, which is above, corresponding more nearly with the superior border. The **inferior** surface [f. inferior] is usually the narrowest of the three. It is covered by peritoneum (continuous with the lower layer of the transverse mesocolon) and is in contact with the duodeno-jejunal angle medially and with coils of jejunum laterally.

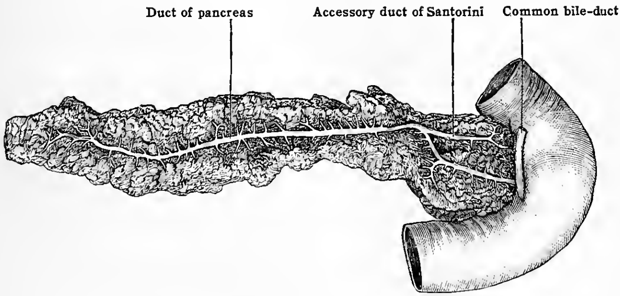
Of the **borders,** the **superior** [margo superior] is related with the splenic artery along its whole length from its origin in the cœliac, and the **posterior** [margo posterior] separates posterior and inferior surfaces. The **anterior** border [margo anterior] is sharp and prominent. It gives attachment to the transverse mesocolon, whose upper layer (belonging to the lesser sac) is continuous with that on the anterior surface of the pancreas, and whose lower layer (belonging to the greater sac) is continuous with that on the inferior surface.

The **tail** of the pancreas [cauda pancreatis] is at the left extremity of the body. It is variable in form, but usually somewhat blunted and upturned. It is almost invariably in contact *laterally* with the medial aspect of the spleen, and *inferiorly* with the splenic flexure of the colon. The splenic vessels often cross from above in front of the tail of the pancreas on their way to join the spleen.

Ducts.—The pancreas has usually two ducts, the main pancreatic duct and the accessory duct. The main *pancreatic* or duct of Wirsung [ductus pancreaticus; Wirsungi] begins in the tail of the pancreas, and extends to the right within the body of the pancreas, about midway between upper and posterior borders, but nearer the posterior surface (figs. 922, 957). It runs a slightly sinuous course receiving branches all along, which enter nearly at right angles. It is largest in the head of the pancreas (diameter about 3 mm.) where it turns obliquely downward. As it approaches the duodenum, it is joined by the common bile duct, the two running side by side. They pass obliquely through the wall of the duodenum for a distance of about 15 mm. (usually causing a fold of the mucosa, the plica longitudinalis duodeni). They terminate finally, usually by a common aperture, but sometimes separately, on the duodenal *papilla major*, as described in connection with the interior of the duodenum. The common aperture is somewhat narrow, but just preceding this the duct is frequently dilated, forming what is called the *ampulla of Vater*.

The *accessory* pancreatic duct (duct of Santorini) is nearly always present (figs. 922, 957), but variable. This duct is small, and lies within the head of the pancreas. At its left end, it usually joins the main duct in the neck of the pancreas. From here it extends nearly horizontally across to the upper part of the descending duodenum and, piercing its wall, usually ends upon the small *papilla minor*, about 2 cm. above and slightly ventral to the papilla major. The relations of the ducts are explained later under development.

Fig. 957.—The Pancreas and its Ducts, Dissected from Behind.



Blood-vessels.—The pancreas receives blood chiefly from the splenic artery through its pancreatic branches, and from the superior mesenteric and hepatic by the inferior and superior pancreatico-duodenal arteries, which form a loop running around, below, and to the right of its head.

The blood is returned into the portal vein by means of the splenic and superior mesenteric veins.

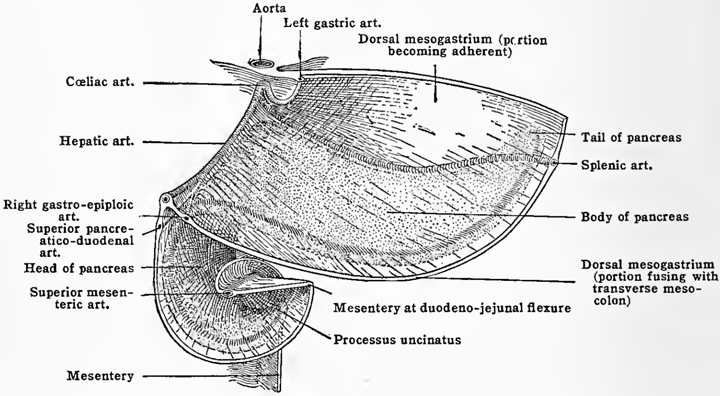
Lymphatics.—The lymphatics terminate in numerous glands which lie near the root of the superior mesenteric artery, above and below the neck of the pancreas. All the lymphatics drain ultimately into the cœliac glands.

Nerves.—These are branches of the cœliac plexus which accompany the arteries entering the gland. The main part of the cœliac plexus lies behind the gland.

Minute anatomy.—In many respects, the pancreas resembles the salivary glands in structure, hence its German name 'Bauchspeicheldrüse' ('abdominal salivary gland'). The gland proper is racemose (or tubulo-racemose) in structure, the secreting cells characteristically granular and 'serous' in type. The thin-walled 'intercalary ducts,' often invaginated to form 'centroacinar' cells, are characteristic. The lobules are very loosely joined by areolar tissue, and there is no distinct fibrous capsule around the gland. The most important of the distinctive characters of the pancreas is the presence throughout the gland of numerous small interlobular cell-masses of varied form and size—the *islets of Langerhans* (fig. 959). These have no ducts, but are richly supplied with blood-vessels. They are ductless glands of great importance in sugar metabolism, and their removal or disease produces diabetes. While derived embryologically from the same entodermal anlage which gives rise to the pancreas gland proper, they apparently have no direct connections with it in the adult. The question as to the possible metamorphosis of acini into islets, or *vice versa*, under certain conditions (e. g., hunger) in the adult has been much disputed. Bensley, however, has recently presented strong evidence against this view.

Development of the pancreas.—The pancreas has its origin in three entodermal buds, one of which (the dorsal anlage) grows from the dorsal portion of the duodenum, the other two (ventral anlages) from either side of the bile-duct. Of the two latter, only that growing from the right side of the bile-duct needs further consideration, as the other soon disappears. The dorsal anlage grows at first more rapidly than the ventral, which arises from the bile-duct. In their further growth both the dorsal and ventral anlages become lobed, these lobes dividing further to form the ducts and the alveoli of the gland. By about the end of the second month the distal end of the ventral portion comes in contact with the dorsal portion at a short distance from the latter's connection with the duodenum. A fusion of the two portions thus takes place in this region, and at the same time there is established by anastomosis a connection between the terminal branches of the main duct of the dorsal portion—duct of Santorini—and the branches of the main duct of the ventral portion—the duct of Wirsung. With further development the duct of Wirsung develops into the main pancreatic duct, the duct of the dorsal

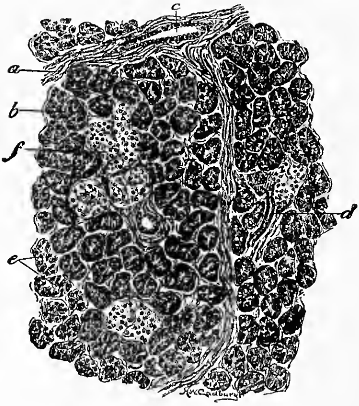
Fig. 958.—Diagram Showing the Relations of the Pancreas to the Primitive Mesentery. (Poirier-Charpy.)



portion (duct of Santorini) either losing its connection with the duodenum or remaining as the accessory pancreatic duct.

Thus of the adult gland, only the lower portion of the head is derived from the primitive ventral anlage, although the duct of the latter drains nearly the entire adult gland. The upper part of the head of the pancreas, and all of the body and tail are derived from the dorsal anlage; although most of its duct joins with the duct of Wirsung to form the main pancreatic duct, only a small part persisting as the accessory duct of Santorini.

Fig. 959.—Section of Human Pancreas, Magnified, Showing Several Islets of Langerhans. (Radasch.) *a*, Interlobular connective tissue, containing an interlobular duct, *c*, *b*, Capillary. *d*, Interlobular duct. *e*, Alveoli. *f*, Islet of Langerhans.



During the early stages in the development of the pancreas the entodermal buds from which it forms grow into the mesoduodenum, and later the dorsal mesogastrium. With the rotation of the stomach and the consequent change in the position of the mesogastrium and its partial fusion with the abdominal wall, the pancreas assumes a retroperitoneal position. This is illustrated by fig. 958. The head of the pancreas is involved in the rotation of the primitive intestinal loop counter-clockwise around the superior mesenteric artery. This accounts for the position and the hook-like form of the processus uncinatus. Following this rotation, the duodenum and the head of the pancreas become pressed backward against the posterior abdominal wall, where they become adherent, with fusion and obliteration of the primitive peritoneum. The body of the pancreas, extending into the dorsal mesogastrium (fig. 900), is similarly caught in the pouch-like downgrowth of the latter to form the bursa omentalis (lesser sac), and is thereby carried over to the left side. When the posterior layer of the primitive bursa fold becomes fused with the posterior abdominal wall, the enclosed pancreas is likewise fixed and becomes retroperitoneal. Of these obliterated peritoneal layers of the embryo, only certain layers of fascia remain as their representatives in the adult. From the lower aspect of the pancreas downward, the posterior layer of the bursa fold becomes fused with the transverse mesocolon, so that in the adult the latter appears to arise from the anterior border of the pancreas (fig. 904).

Variations.—Aside from minor fluctuations in size and form, the variations of the pancreas are chiefly congenital and of embryonic origin. Cases of *accessory or supernumerary pancreas* are not rare. They are usually of small size and have separate ducts. They may occur along the wall of the duodenum, or even in the stomach or jejunum. They are perhaps in some way connected with the numerous intestinal diverticula which occur in the embryo. *Divided pancreas* differ from the accessory in that a mass of the pancreas becomes separated from the main gland, connected only by a duct. This occurs oftenest in the region of the tail (sometimes extending into the spleen) or of the processus uncinatus, forming what is termed a 'lesser pancreas.' Sometimes a ring of glandular tissue from the head of the pancreas surrounds the descending duodenum, forming an *annular pancreas*. Variations in the *direction* of the body are numerous; it may be horizontal, ascending or bent in various ways. These are doubtless congenital variations, as similar types have been described in the fœtus (Jackson). It has been experimentally demonstrated that varying degrees of distention of the stomach and intestines affect profoundly the *form of the body* of the pancreas. When the stomach alone is distended, the pancreas is flattened antero-posteriorly, the inferior surface being practically obliterated. When *both* stomach and intestines are distended, the pancreas is flattened from above downward, and extends forward like a shelf, the posterior surface being much reduced (Jackson). Numerous variations in the *ducts* are easily understood from their complicated development. The accessory duct (of Satorini) is in the fœtus as large as the main duct (of Wirsung), the preponderance of the latter being established later. The accessory duct in the adult may be larger than usual, and retain its primitive drainage, or even drain the entire gland in rare cases where the duct of Wirsung is absent. Or the accessory duct may be rudimentary or (rarely) absent. Similar variations occur in the main duct of Wirsung. Rarely the pancreas may open into the duodenum by three ducts, probably representing three embryonic anlages. Abnormalities of the pancreas are often associated with duodenal diverticula.

Comparative.—The pancreas, like the liver, is constant throughout the vertebrates. It always arises by budding off from the endodermal epithelium of the intestine, closely associated with the liver. There is typically a triple anlage (rarely multiple, which is perhaps the ancestral type), with one dorsal and two ventral outgrowths. These fuse and form the adult pancreas in a variety of ways. In many of the fishes, the pancreas is very small, diffuse and inconspicuous, sometimes embedded in the liver or intestinal wall. Of the three primitive ducts, usually only two persist (as in man), but often only one, or all three (in birds). All three types occur in mammals. The islets of Langerhans arise from the epithelial pancreas anlage, and appear to be constantly present, even in the lowest vertebrates. Laguesse even considers that phylogenetically they form the most primitive part of the pancreas, but this is doubtful.

SECTION X

THE RESPIRATORY SYSTEM

Revised for the Fifth Edition

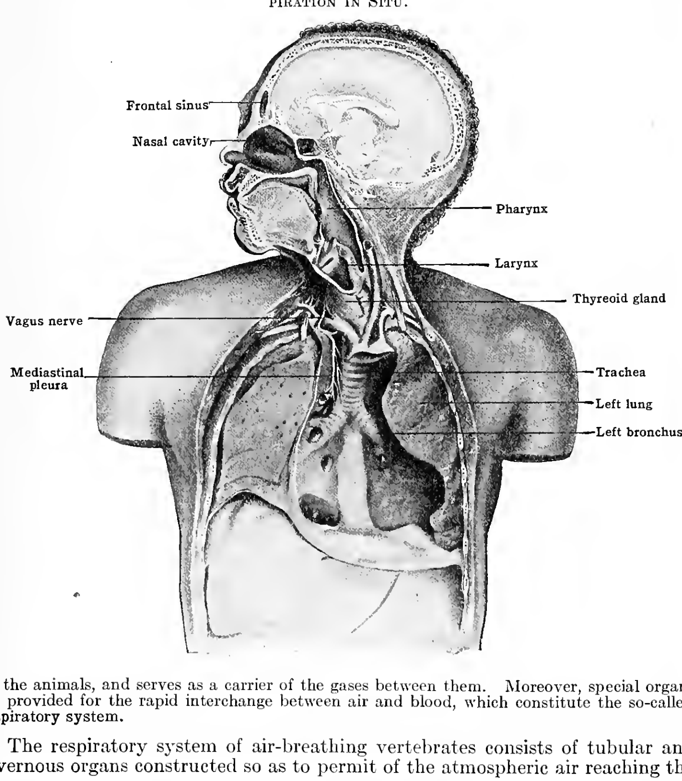
By R. J. TERRY, A.B., M.D.,

PROFESSOR OF ANATOMY IN WASHINGTON UNIVERSITY

RESPIRATION consists in the absorption by the organism of oxygen and the discharge of a waste-product, carbon dioxide.

Among unicellular animals the oxygen is taken up directly from the medium—water or air—in which they live, and the carbon dioxide given off into it. With the cells which make up the body of higher animals the principle is the same, but the interchange of gases is indirect. The blood stands as an intermediate element between the cells of the body and the medium inhabited

Fig. 960.—Dissection of a Male Negro, Age 43 Years, to Show the Organs of Respiration in Situ.



by the animals, and serves as a carrier of the gases between them. Moreover, special organs are provided for the rapid interchange between air and blood, which constitute the so-called **respiratory system.**

The respiratory system of air-breathing vertebrates consists of tubular and cavernous organs constructed so as to permit of the atmospheric air reaching the blood circulating in the body. The essential organs in the system are the paired **lungs** located in the **thoracic cavity.** Air is carried to and from the lungs by the **trachea** and **bronchi,** and these simple transmitting tubes are in turn put into communication with the exterior by the mediation of other organs. The latter are, however, specially constructed in adaptation to other functions in addition to those relating to respiration: the **larynx** for the production of the voice, the **pharynx** and **mouth** in connection with alimentation, the **nasal cavity** and **external nose** functioning in the sense of smell. (For the description of the mouth and pharynx see Section IX; for the olfactory organ see Section VIII.)

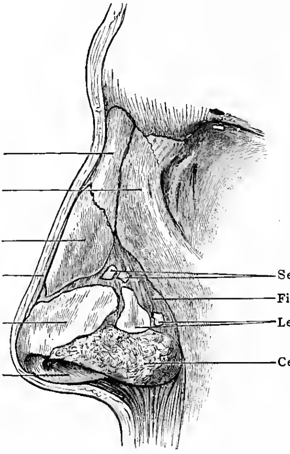
The organs of circulation are always adapted to the form of the respiratory apparatus, and among all higher animals a connection is established between heart and lungs by the pulmonary artery, which carries venous blood to the latter, and by the pulmonary veins, which convey arterial blood from the lungs to the heart, whence the aorta takes it into the general circulation.

In their origin and development the respiratory organs are closely associated with or differentiated from the beginnings of the digestive apparatus. Thus the processes of the early development of the nasal cavity and mouth are interdependent; the origin of the greater part of the larynx, the trachea and lungs is by ventral outgrowth of the entodermal canal.

THE NOSE

The **external nose** [nasus externus] (fig. 961), shaped like a triangular pyramid, is formed of a bony and cartilaginous framework covered by muscles and the integument of the face externally and lined within by periosteal and perichondral layers overspread by mucous membrane. At the forehead, between the eyes, is

Fig. 961.—The Left Side of the External Nose, showing its Cartilages, etc.



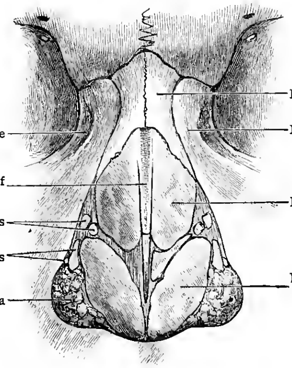
the **root** of the nose [radix nasi], and from this, extending inferiorly and anteriorly, is a rounded ventral border, the **dorsum** of the nose [dorsum nasi], which may be either straight, convex, or concave, and which ends inferiorly at the **apex** of the nose [apex nasi]. The superior part of the dorsum is known as the bridge. Inferiorly, overhanging the upper lip, is the **base** of the nose [basis nasi] which presents two orifices, the **nares** or nostrils, separated from one another by the inferior movable part of the nasal septum [septum mobile nasi].

The nostril of man is remarkable on account of its position, facing as it does almost directly downward. It is oval in form, with the long axis directed antero-posteriorly, or approximately so, in Europeans. The size of the nostril is under the control of muscles (see p. 334) and may be dilated or constricted by their action.

The sides of the nose slope from the dorsum laterally and posteriorly, and below ferminate on each side in the **margin** of the nose [margo nasi]; posteriorly and inferiorly the sides are expanded and more convex, forming the **alæ nasi.** Each of these is separated from the rest of the lateral surface by a sulcus, and the inferior free margin of each bounds a naris laterally.

Three types of nose, distinguished by differences in the proportion of breadth and length are recognised by anthropologists: the leptorrhine or long, high nose; the platyrrhine or short, low nose; the mesorrhine, a form intermediate between the other two. The leptorrhine type prevails among white races, the platyrrhine in the black peoples and the mesorrhine in the red and yellow races.

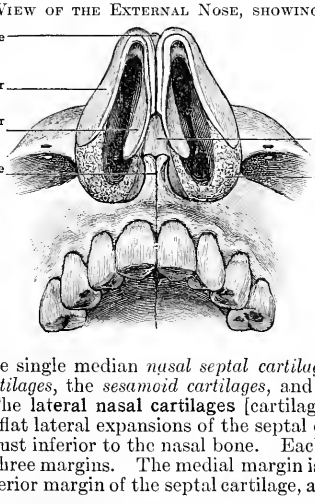
Fig. 962.—Anterior View of the External Nose, showing its Cartilages, etc.



The framework of the external nose is formed partly of bone and partly of hyaline cartilage The bones, which form only the smaller superior part, are the two nasal bones and the fronta processes and anterior nasal spines of the two maxillæ (pp. 87, 108).

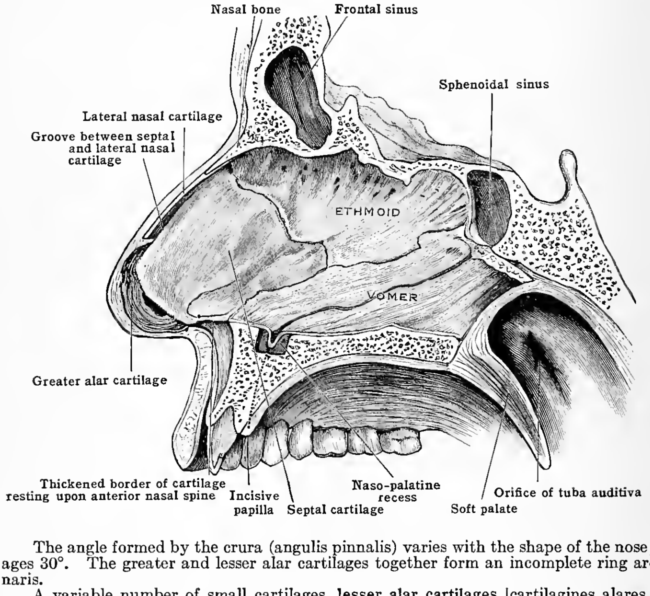
The nasal cartilages [cartilagines nasi] are located about the piriform aperture and constitute the larger part of the nasal framework. There are five principal cartilages: superiorly, the two *lateral nasal cartilages,* inferiorly the two *greater*

Fig. 963.—Inferior View of the External Nose, showing its Cartilages, etc.



alar cartilages, and the single median *nasal septal cartilage.* Beides these there are the *lesser alar cartilages,* the *sesamoid cartilages,* and the *vomero-nasal cartilages* of Jacobson. The **lateral nasal cartilages** [cartilagines nasi laterales] are triangular and nearly flat lateral expansions of the septal cartilage, placed one on each side of the nose just inferior to the nasal bone. Each presents an inner and an outer surface and three margins. The medial margin is continuous in its superior third with the anterior margin of the septal cartilage, and through this with its fellow of the opposite side, but it is separated inferiorly from the septal cartilage by a narrow cleft. The curved supero-lateral margin is firmly attached by strong fibrous tissue to the nasal bone and frontal process of the maxilla, and underlies these bones for a considerable distance, especially near the septum. The inferior margin is connected by fibrous tissue to the greater alar cartilage. The **greater alar cartilages** [cartilagines alares majores], variable in form, are situated one on each side of the apex of the nose (figs. 961, 963). Each is thin, pliant, curved, and so folded that it forms a medial and a lateral crus, which bound and tend to hold open each naris. The **medial crus** [crus mediale] is loosely attached to its fellow of the opposite side, the two being situated inferior to the septal cartilage and forming the tip of the nose and the inferior part of the mobile septum. The **lateral crus** [crus laterale] joins the medial crus at the apex of the nose; it is somewhat oval in shape, and curves dorsally in the superior and anterior portion of the ala. It is connected posteriorly to the nasal margin of the maxilla by a broad mass of dense fibrous and fatty tissue, and helps to maintain the contour of this part of the nose.

Fig. 964.—Medial Wall of the Nasal Cavity, the Mucous Membrane Being Removed. The dotted line indicates the course of the incisive canal.



The angle formed by the crura (angulis pinnalis) varies with the shape of the nose; it averages 30°. The greater and lesser alar cartilages together form an incomplete ring around the naris.

A variable number of small cartilages, **lesser alar cartilages** [cartilagines alares minores] are found in the fibrous tissue of the ala, and in the interval between each greater alar and lateral cartilage occur one or more small plates, **sesamoid cartilages** [cartilagines sesamoideæ] (fig. 961).

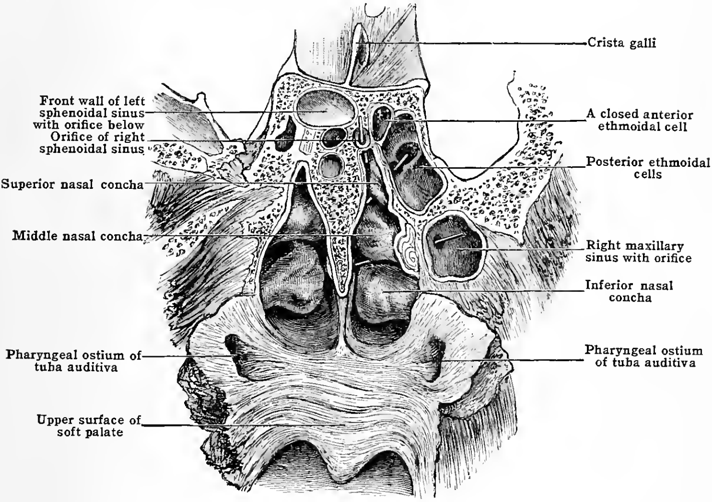
The **septal cartilage** [cartilago septi nasi] (fig. 964) forms the anterior part of the septum. It is quadrilateral in shape and fits into the triangular interval of the bony septum. Its antero-superior margin in its upper part meets the internasal suture. Inferior to the nasal bone it presents a shallow groove which gradually narrows toward the tip of the nose, and whose borders are continuous superiorly with the lateral nasal cartilages, but are separated from their inferior two-thirds by a narrow slit. The most inferior part of this margin of the septal cartilage is placed between the greater alar cartilages. The antero-inferior margin extends backward from the rounded anterior angle to the anterior nasal spine. Inferiorly it is attached to the medial crus of the greater alar cartilage and to the mobile nasal septum. The postero-superior margin is attached to the perpendicular plate of the ethmoid, and the postero-inferior margin joins the vomer and the ventral part of the nasal crest of the maxilla, the cartilage broadening out to obtain a wide though lax attachment to the nasal spine.

The shape of the septal cartilage varies with the extent of the ossification of the bony septum. Even in the adult a strip of cartilage may extend for a varying distance postero-superiorly between the vomer and perpendicular plate of the ethmoid, sometimes reaching the body of the sphenoid; it is known as the **sphenoidal process** of the septal cartilage [processus sphenoidalis septi cartilaginei]. The **vomero-nasal cartilage** [cartilago vomero-nasalis Jacobsoni*] is a narrow strip of cartilage firmly attached to each side of the septal cartilage, where this joins the anterior portion of the vomer.

Muscles.—The muscles are grouped according to function as dilators and contractors, the latter being comparatively feeble in their action. They are described on p. 334.

The **skin** covering the external nose is thin and freely movable upon the subjacent parts, except at the tip and over the cartilages, where it is much thicker,

FIG. 965.—OBLIQUE SECTION PASSING THROUGH THE NASAL CAVITY JUST IN FRONT OF THE CHOANÆ. (Seen from behind.)



more adherent, and furnished with numerous exceptionally large sebaceous glands. At the nares it is reflected into the nasal cavity, where it passes into the mucous membrane. The hairs on the skin of the nose are very fine, except in the nares, where they may be strongly developed.

Vessels and nerves.—The arteries of the external nose are derived from the external maxillary (facial) artery (pp. 540 and 541), the ophthalmic artery (p. 554), and the infra-orbital artery (p. 549). The veins terminate in the anterior facial vein and the ophthalmic vein (p. 644). The **lymphatics** pass to the submaxillary lymphatic nodes (p. 712). The **motor nerves** are branches of the facial (p. 946). The **sensory nerves** are derived from the trigeminal through the frontal and naso-ciliary branches of the ophthalmic (p. 936) and infra-orbital branch of the maxillary (p. 939).

The **nasal cavity** [cavum nasi] is the ample space situated between the floor of the cranium and the roof of the mouth extending forward into the external nose and backward to the nasal part of the pharynx. With the exception of the inferior part of the nose its walls are of bone as already described (pp. 110, 112). The cartilages and membranes of the nose complete the boundaries anteriorly. Here the cavity opens to the exterior by the nares. At the back a free communi-

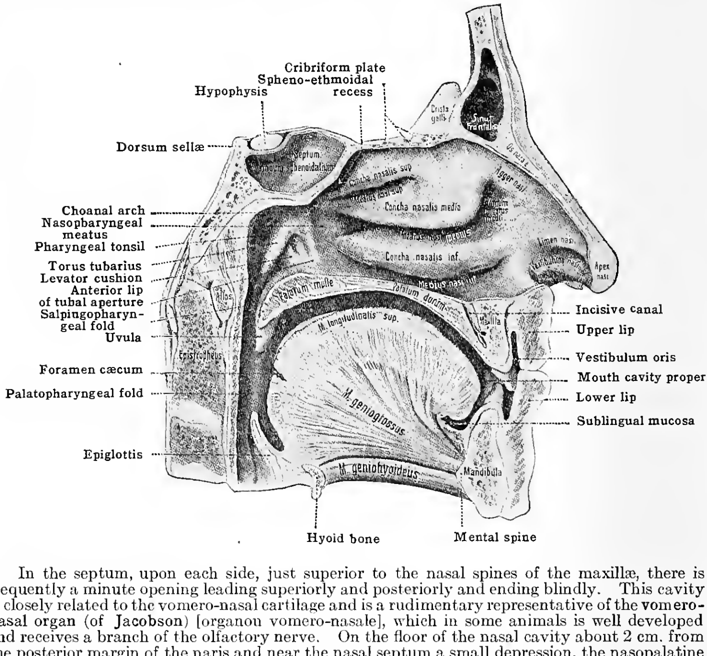
* Jacobson: Danish anatomist. B. 1783, D. 1843.

cation with the pharynx is established through the paired choanæ. Furthermore accessory nasal cavities, the paranasal sinuses, open into the cavum nasi. The walls of the nasal cavity are covered with periosteum and mucosa, the latter presenting important differences in the respiratory and olfactory regions. The organ of smell, included in the nasal cavity, is described on p. 1049.

The cavum nasi is divided into right and left symmetrical parts, called the nasal fossæ, by the **septum** of the nose [septum nasi]. The latter is supported by a framework composed of the *osseous septum* [septum nasi osseum] posteriorly, and the *cartilaginous septum* [septum cartilagineum] anteriorly. Antero-inferiorly, the small movable part of the septum is also called the *membranous septum* [septum membranaceum].

The nasal septum is almost always straight in primitive races and Caucasian children; but in a large proportion of Caucasian adults it is deflected to one side or the other.

Fig. 966.—Sagittal Section through the Facial Part of the Head and the Bodies of the upper three Cervical Vertebrae. The section lies to the right of the median plane. The nasal septum has been removed. (Rauber-Kopsch.)



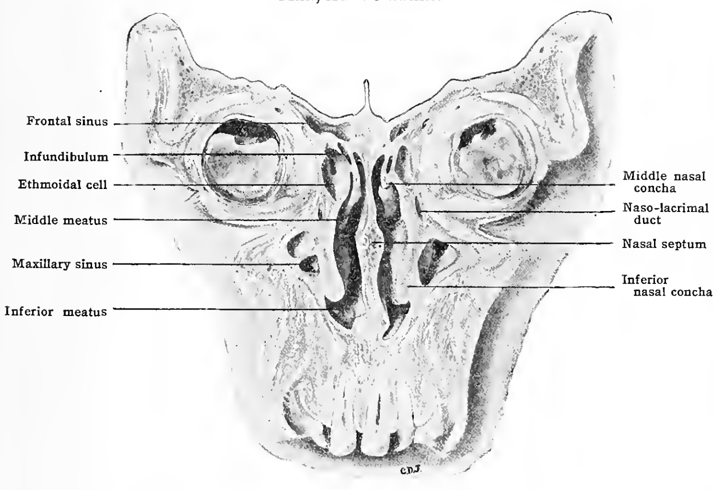
In the septum, upon each side, just superior to the nasal spines of the maxillæ, there is frequently a minute opening leading superiorly and posteriorly and ending blindly. This cavity is closely related to the vomero-nasal cartilage and is a rudimentary representative of the **vomeronasal organ (of Jacobson)** [organon vomero-nasale], which in some animals is well developed and receives a branch of the olfactory nerve. On the floor of the nasal cavity about 2 cm. from the posterior margin of the naris and near the nasal septum a small depression, the nasopalatine recess, is often seen. This is the mouth of the incisive duct [ductus incisivus] which leads into the incisive canal for a greater or less distance and may even extend to the mouth, where its termination is marked by the incisive papilla. The incisive duct indicates the position of a foramen which in the embryo connected the mouth and nose.

The naris leads upward into the **vestibule** of the nose [vestibulum nasi], the small cavity within the compass of the greater alar cartilage. Its walls are lined with skin beset with the large hairs called **vibrissæ** and containing many sebaceous glands. The vibrissæ serve to protect the nasal cavity from the entrance of foreign matter. On the lateral wall, the vestibule is marked off from the rest of the nasal cavity by a distinct ridge, the **limen nasi,** corresponding to the superior margin of the greater alar cartilage. On the lateral wall of the cavity within the limen nasi are three antero-posterior ridges, the **superior, middle,** and **inferior**

conchæ (fig. 966). These have a bony framework (described on pp. 83, 110) and are covered by the mucous membrane of the nose. The conchæ are not parallel to one another but converge in a backward direction. The **superior nasal concha** [concha nasalis superior] is the smallest, projects only slightly medialward and downward from the upper, posterior part of the lateral wall, overhanging the groove called superior meatus of the nose. The **middle nasal concha** [concha nasalis media] is extensive, reaching from the fore part to the posterior confines of the lateral wall. Its free margin is nearly vertical in its anterior one-fourth, horizontal and laterally rolled in the rest of its extent. Under cover of this concha runs the middle meatus. The **inferior nasal concha** [concha nasalis inferior] is the longest, has a lateral attached and an inferior laterally rolled free margin running near the floor of the nasal cavity. Beneath it lies the inferior meatus.

Meatuses of the nose [meatus nasi] (figs. 966, 968). The name **common meatus** of the nose [meatus nasi communis] is given to that part of the nasal cav-

Fig. 967.—Frontal Section through the Facial Portion of the Head of a White Man, Age 28 Years.



ity which lies between the septum nasi and the nasal conchæ and stretches from floor to roof. The three meatuses under cover of the nasal conchæ have been mentioned. These passages all communicate freely with the common meatus, extend antero-posteriorly and have a greater capacity in front than behind. The **superior meatus** [meatus nasi superior] is the smallest of the three. Into it open the posterior ethmoidal cells by one or two small foramina. The spheno-palatine foramen, which communicates with the meatus in the dry skull, is entirely covered up by mucous membrane. The **middle meatus** [meatus nasi medius] is a much larger passage. Upon its lateral wall is a rounded eminence, the **ethmoidal bulla,** caused by the middle ethmoidal cells and perforated by the opening into them. Inferior to this is a deep curved groove, the **hiatus semilunaris,** which is continued superiorly by the **ethmoidal infundibulum** [infundibulum ethmoidale] into the frontal sinus. It also receives the openings of the anterior ethmoidal cells and the **maxillary sinus.** The **inferior meatus** [meatus nasi inferior] is the longest of the three. Upon its lateral wall, just inferior to the attachment of the inferior concha, is the slit-like opening of the **naso-lacrimal duct** [ductus naso-lacrimalis], around the opening of which the mucous membrane forms a valve, the **plica lacrimalis** (Hasneri).

Recent investigation of the nasal conchæ indicates that two upper conchæ (concha nasalis superior and concha nasalis suprema [Santorini]) are more often present than one. Three upper conchæ are not rare.

The attached margins of the middle and inferior conchæ are both arched, the convexities being upward. The highest point of the convexity is near the middle of the attached margin in the inferior concha and lies about 17 mm. above the floor of the nose; the anterior end of this concha is approximately 25–35 mm. distant from the apex of the nose (Kallius).

From the anterior end of the middle concha a slight variable elevation of the mucous membrane of the nose extends forward and downward. This, the **agger nasi**, which is regarded as of constant occurrence in the new-born, appears to be a rudimentary representative of the nasoturbinale of mammals (Schwalbe).

Below the agger nasi a broad depression of the lateral wall, the **atrium meatus medii**, leads posteriorly beneath the anterior free margin of the middle concha to the middle meatus, while above the agger, between it and the roof of the nasal cavity, the slight **olfactory groove** [sulcus olfactorius] ascends upon the lateral wall to the olfactory region. In this region, above the superior concha, is a corner of the nasal cavity of interest on account of the sphenoidal sinus opening into it: this is the **spheno-ethmoidal recess** [recessus spheno-ethmoidalis].

Variation in the number and position of the openings into the meatuses is of practical interest. An accessory mouth of the maxillary sinus is rather frequently met with, especially in old people; it lies most commonly behind the hiatus semilunaris. The infundibulum ethmoidale may open independently of the hiatus semilunaris at a spot beneath the anterior end of the attached margin of the middle concha. In the inferior meatus the mouth of the naso-lacrimal duct, which is found 22–25 mm. behind the posterior margin of the nares, may have one or more accessory openings associated with it; these are perforations of the plica lacrimalis.

Communication between the nasal cavity and the nasal part of the pharynx is effected by means of the paired **posterior apertures [choanæ]**. These are oval in form, their height greater than their width. They are located at either side of the posterior edge of the nasal septum and are limited above by the body of the sphenoid, below by the line of junction of the hard and soft palate.

From the plane of the choana forward a rather constricted portion of the nasal cavity extends for a short distance to reach the level of the posterior ends of the middle and inferior conchæ. Into this region, which is known as the **meatus naso-pharyngeus**, open posteriorly the superior, middle and inferior meatuses. Posterior rhinoscopic examination reveals the choanæ, the naso-pharyngeal meatus, the posterior extremities of the three conchæ and of the meatuses beneath them.

Dimensions of the nasal cavity.—The length of the floor averages approximately 40 mm., the width 32 mm., the height from floor to lamina cribrosa 47 mm. The length of the lateral wall is about 63 mm. The choana measures 29.8 mm. high and 15.5 mm. broad. The area of the two nares is 2 sq. cm.

Paranasal sinuses [sinus paranasales] (figs. 964-968).—The location, form and relations of the bony-walled spaces connected with the nasal cavity have been fully described in the section on OSTEOLOGY. The conditions observed in the living subject differ in certain respects from those present in the macerated skull; the spaces are lined by a mucous membrane which, though affecting but slightly the form of these chambers, modifies considerably the openings by which they communicate with the nasal cavity. These openings permit the entrance and exit of air and to some extent the escape of fluids which may accumulate in the sinuses. While the significance of these spaces is not at present clear it is, however, certain that they function in lightening the weight of the skull, and probable that indirectly they serve in connection with the sense of smell.

Maxillary sinus (of Highmore*) [sinus maxillaris Highmori] (figs. 965, 966, 967). Entrance into the maxillary sinus is offered through the middle part of the hiatus semilunaris, that is, the deep, narrow notch between the ethmoidal bulla and uncinate process of the ethmoid. Viewed from within the sinus, the opening appears as an oval window in the upper part of the medial wall—a position unfavourable to the discharge of matter, when the body is in the upright posture. An accessory opening, situated behind the normal ostium, is present in about 10 per cent. of cases.

Measurements of 90 specimens of the adult sinus maxillaris gave as the average the following (Schaeffer):

Dorsosuperior diagonal	38 mm.
Ventrosuperior diagonal	38.5 mm.
Superoinferior	33 mm.
Ventrodorsal	34 mm.
Mediolateral	23 mm.

Increase in capacity of the maxillary sinus is sometimes observed as the result of more or less extensive excavation of the bony processes of the maxilla adjacent to it, viz.: the alveolar, palatal, frontal and zygomatic. On the other hand narrowing of the cavity is encountered,

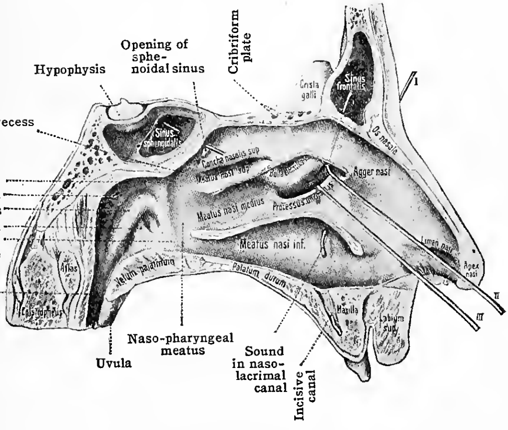
* Highmore, Nathaniel: English physician. B. 1613, D. 1685.

caused by unusually thick walls of bone, bulging inward of the facial or nasal walls, and through retention of teeth. Incomplete division into two parts through the presence of a septum has several times been observed. Communication with ethmoidal cells and with the cavity of the orbital process of the palate bone sometimes exists.

Frontal sinus [sinus frontalis] (figs. 78, 964, 968).—The paired frontal sinuses, separated from each other by a bony septum, have in general the shape of a three-sided pyramid with the base below and the apex formed above in the frontal squama. In the base near the septum is located the superior aperture of the infundibulum which, it will be recalled, opens inferiorly at the anterior extremity of the hiatus semilunaris.

The form and size of the frontal sinuses are exceedingly variable. They may extend backward in the orbital part of the frontal bone as far as the suture between it and the small wing of the sphenoid; laterally into the zygomatic process; upward toward the coronal suture. The capacity of the sinus, as determined in a small number of cases, varied from 3 to 7.8 ccm. (Brühl). Asymmetry of the septum is frequently observed. Absence of one of the sinuses is not a rare condition; absence of both is occasionally encountered.

Fig. 968.—Left Nasal Cavity. (Rauber-Kopsch.)



Ethmoidal cells [cellulæ ethmoidales] (figs. 965, 968).—The openings of the anterior cells into the semilunar hiatus and infundibulum, and of the posterior cells at the superior meatus have already been described.

Communications between the ethmoidal cells and the sphenoidal and maxillary sinuses are not rare; the cavity in the orbital process of the palate bone may open into the posterior cells. In old age, foramina through the lamina papyracea may appear, leading to the introduction of air into the orbit.

Sphenoidal sinus [sinus sphenoidalis] (figs. 964, 965, 966).—The apertures of the paired sphenoidal sinuses are, on account of the mucous membrane covering, much smaller than they are in the dried skull. They lie in the anterior wall near the septum, nearer the roof than the floor, and open into the spheno-ethmoidal recess.

Extension of the sphenoidal sinuses backward and also into neighbouring processes, and communication with ethmoidal cells and with the small cavity of the orbital process of the palate are not unusual. The capacity of the sinus varies between 1 and 4.2 ccm. (Brühl).

Functions of the paranasal sinuses.—Various functions have been attributed to the sinuses near the nose, none of which is entirely satisfying. Mediæval anatomists proposed that these cavities contributed to the resonance of the voice, or that they supplied the mucus by which the nasal cavity is kept moist. Lightening the skull, warming the inspired air and taking part, indirectly, in the sense of smell are functions assigned by anatomists of later times.

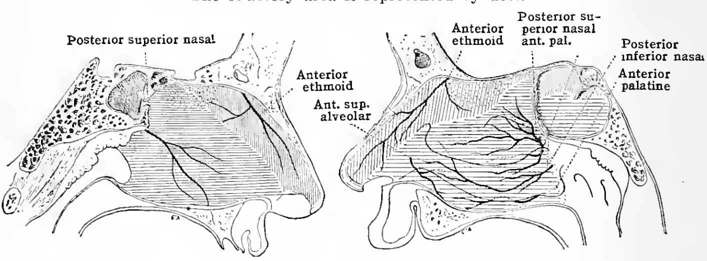
The **mucous membrane** of the nose [membrana mucosa nasi].—The nasal cavity is completely lined with mucous membrane, which inferiorly, at the limen nasi blends with the skin covering the walls of the vestibule (p. 1204). Posteriorly it joins the mucous membrane of the pharynx and palate. It covers some of the openings which are seen in the bony walls; those apertures, however, which lead into the paranasal-sinuses and into the naso-lacrimal duct remain patent, although as already stated the bony openings are much reduced in size.

In the nasal cavity the bright rose-red vascular mucous membrane is tightly bound to the periosteum and perichondrium, and is covered with a ciliated columnar epithelium. Numerous large mucous **nasal glands** [glandulæ nasales] pour their more or less watery secretion over the entire surface. A very considerable venous plexus is found in many parts of the nasal mucosa. Over the inferior concha and to a less extent in the mucosa of the middle and superior conchæ, it forms the **cavernous plexuses** of the **conchæ** [plexus cavernosi concharum] contributing to build up about these bodies a true erectile tissue. The thickness which these glands and venous plexuses give to the mucous membrane of the conchæ causes the marked increase in size of these bodies over that of their bony supports. The region covered by the mucous membrane just described forms the greater part of the nasal cavity, and is known as the **respiratory region** [regio respiratoria]. The mucous membrane of a small area over the superior concha and the adjacent septal wall (fig. 969) has a somewhat different structure. In this area the olfactory nerves are distributed, whence it is known as the **olfactory region** [regio olfactoria] and its mucous membrane, compared with that of the respiratory region, is less vascular, yellow or yellowish-brown in colour, and covered by a non-ciliated epithelium. Its cells, specially modified, some of which are directly connected with the olfactory nerve, form the **olfactory organ** [organon olfactus]. Small mucous **olfactory glands** [glandulæ olfactoriæ] occur in the region. The mucous membrane which lines the paranasal sinuses throughout is a continuation of the nasal mucosa; it is, however, paler, less vascular, somewhat thinner, and more loosely attached to the bones. Mucous glands are numerous.

The waving of the cilia in the nasal cavity is such as to sweep foreign matter toward the choanæ; in the paranasal sinuses, toward the nasal cavity.

Fig. 969.—Diagram of the Distribution of the Nerves in the Nasal Cavity. (Poirier and Charpy.)

The olfactory area is represented by dots.



Vessels and nerves.—The **arteries** of the nasal cavity are the spheno-palatine artery from the internal maxillary which, through its posterior lateral nasal branches, supplies the middle and inferior conchæ (p. 549), the anterior and posterior ethmoidal arteries from the ophthalmic (p. 553), the descending palatine artery from the internal maxillary (p. 549), and the superior labial branch of the external maxillary to the vestibule. The **venous plexuses** of the mucous membrane are drained posteriorly by the spheno-palatine to join the pterygoid plexus, superiorly by the anterior and posterior ethmoidal veins to join the superior ophthalmic vein, and anteriorly by small branches to join the facial. The **lymphatics** form a well-developed plexus which is said to communicate indirectly, through the lymphatics surrounding the olfactory nerves, with the subdural and subarachnoid spaces. Posteriorly two or more well-developed trunks communicate with the pharyngeal lymphatics, and anteriorly the nasal lymphatics join with the lymphatics of the face. The **olfactory nerves** pass through the cribriform plate of the ethmoid bone and are distributed to the olfactory area (p. 929). The **trigeminal nerve** furnishes the following branches to the nasal cavity:—branches from the naso-ciliary branch of the ophthalmic nerve; the Vidian nerve; the posterior superior and posterior inferior nasal and the anterior palatine from the spheno-palatine ganglion (p. 962); the anterior superior alveolar from the infra-orbital division of the maxillary nerve (p. 938).

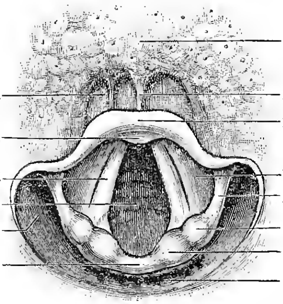
The development of the nose.—The nasal cavity makes its appearance as a depression of the ectoderm on either side of the median line, immediately in front of the oral fossa, with which the depressions are at first continuous. Later, by the union of the maxillary and globular processes (see p. 18), the depressions are separated from the anterior part of the oral fossa, and this separation is continued by the formation of the palatal processes of the maxillæ and palatine bones, so that finally the nasal cavities communicate posteriorly only with the pharynx.

The cartilage which forms the lateral walls of the nasal fossæ is at first quite smooth, but later it becomes eroded by absorption, whereby the nasal conchæ are formed. The erosion also extends into the ethmoid bone, forming the ethmoidal cells, and into the neighbouring bones to form the frontal, sphenoidal, and maxillary sinuses.

THE LARYNX

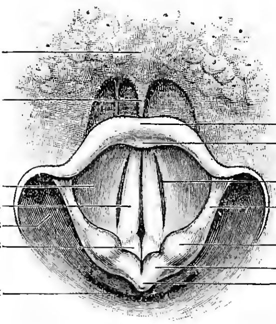
The **larynx** (figs. 960, 970, 971,), is a tubular organ, the framework of which is made of cartilages joined together and of elastic membranes. Its inner surface is covered by mucosa. From the membranes are formed a pair of **vocal folds** which, by the passage of air through the larynx, are thrown into vibration and so function in the generation of sound. These folds are affected in respect to their

Fig. 970.—View of Interior of Larynx as seen from above during Inspiration.



tension and in their mutual relation by the actions of a system of laryngeal muscles under the control of the vagus nerve and are made thereby, on the one hand, to produce those modifications of the sound involved in the voice and on the other hand to regulate the amount of air passing through the **cavity of the larynx.** The latter communicates above with the pharynx by means of the opening called the **laryngeal aperture,** and below with the cavity of the trachea. Figure 970 shows the laryngeal aperture with its boundaries, the **epiglottis** and

Fig. 971.—View of Interior of Larynx as seen from above during Vocalisation.



the **aryepiglottic folds;** also the cavity of the larynx where, on the walls right and left, appear the **ventricular** and vocal folds with the chink called rima glottidis separating them.

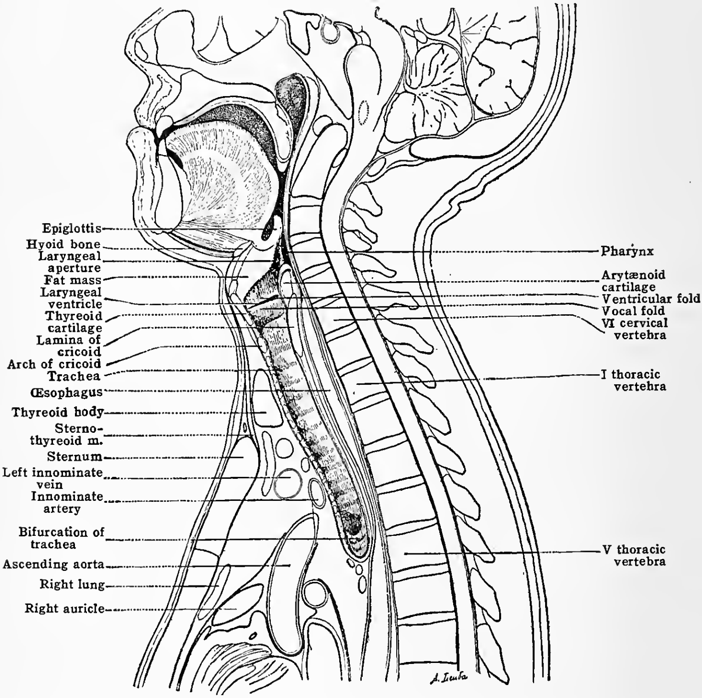
The position of the larynx and some of its important parts can be well seen in a median section (fig. 972).

THE CARTILAGES OF THE LARYNX

The number of cartilages entering into the framework of the larynx is nine, three of which are single and the rest in pairs. Their forms and positions are shown in fig. 973.

The **cricoid cartilage** [cartilago cricoidea] (figs. 973, 974, 975, 978), single, has been compared in its shape to a signet ring. Its position is at the lower end of the larynx, where it is connected with the first ring of the trachea. Posteriorly the cricoid cartilage expands into a broad **lamina** [lamina cartilaginis cricoideæ] which enters into the posterior boundary of the laryngeal cavity, while laterally and in front it forms a narrow **arch** [arcus cartilaginis cricoideæ]. On either side of the upper margin of the lamina is the elliptical **arytænoid articular surface** [facies articularis arytænoidea] its long axis parallel with the margin of the cricoid, its steeply sloping surface convex for articulation with the arytænoid cartilage. The hinder surface of the lamina presents a median ridge and lateral impressions for the attachment of the posterior crico-arytænoid muscles. The arch, weakest

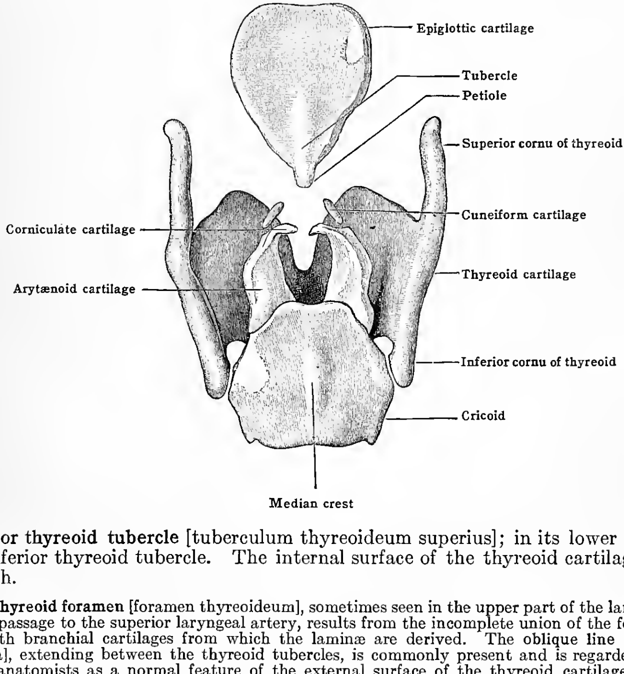
Fig. 972.—Median Section of a Man 21 Years of Age, showing the Position of Larynx and Trachea. (After W. Braune, from Poirier and Charpy.)



in its middle part, presents concave upper and straight lower margins. A circular, elevated **thyreoid articular surface** [facies articularis thyreoidea] for articulation with the inferior cornu of the thyreoid cartilage is situated upon the side of the cricoid where arch and lamina are continuous. The internal surface is covered by the laryngeal mucosa.

The **thyreoid cartilage** [cartilago thyreoidea] (figs. 973, 974, 975, 977), single and the largest in the laryngeal skeleton is composed of two broad **laminæ, right and left,** which meet and are fused anteriorly in the mid-line in a right angle, partly covering the other cartilages laterally and in front. The laminæ are stout, but their connection at the angle is through a weak strip of cartilage. The upper margin of each lamina is convex, and in front drops abruptly to form in the median line the **superior thyreoid notch** [incisura thyreoidea superior]. The anterior edges meeting in the angle produce the **laryngeal prominence** [prominentia laryngea] ("Adam's apple"), which is seen on the front of the neck. The horizontal inferior margin presents near its middle the **inferior thyreoid tubercle** [tuberculum thyreoideum inferius], and in the median line the **inferior thyreoid notch** [incisura thyreoidea inferior]. The thick posterior margin of each lamina is continued above the superior edge in the long **superior cornu** [cornu superius], and below the inferior margin in the short **inferior cornu** [cornu inferius]. The former is directed slightly backward and medialward, and joins with the end of the greater cornu of the hyoid by ligament. The inferior cornu, curving medialward as it descends, articulates by a flat, circular facet upon the medial side of its extremity with the thyreoid articular surface of the cricoid cartilage. The external surface of the lamina affords attachment for muscles and presents in its upper posterior part the

FIG. 973.—CARTILAGES OF THE LARYNX SEEN FROM BEHIND IN THEIR NATURAL POSITIONS. THE CUNEIFORM CARTILAGE IS SOMEWHAT HIGHER THAN NORMAL. (Merkel.)



superior thyreoid tubercle [tuberculum thyreoideum superius]; in its lower part the inferior thyreoid tubercle. The internal surface of the thyreoid cartilage is smooth.

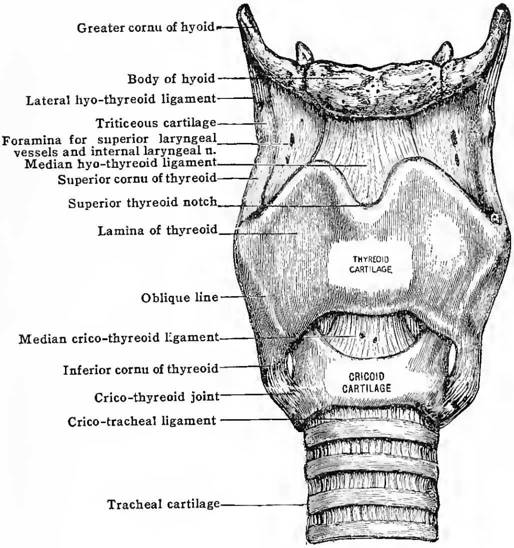
A **thyreoid foramen** [foramen thyreoideum], sometimes seen in the upper part of the lamina, giving passage to the superior laryngeal artery, results from the incomplete union of the fourth and fifth branchial cartilages from which the laminæ are derived. The **oblique line** [linea obliqua], extending between the thyreoid tubercles, is commonly present and is regarded by many anatomists as a normal feature of the external surface of the thyreoid cartilage. It marks the attachment of the sternohyoid and thyreohyoid muscles. At the insertion of the vocal ligaments in the angle of the laminæ a small perichondral process is often observed.

The **arytænoid cartilages** [cartilagines arytænoideæ] (figs. 973, 977, 978, 979), paired, surmount the lamina of the cricoid cartilage and give attachment to the vocal ligaments, whose relations and state of tension are altered by the changes in position which these cartilages are almost constantly undergoing.

Each cartilage is pyramidal in form, and moulded for the attachment of several muscles. The **apex,** which is above, is bent backward and medialward and is connected with a corniculate cartilage. The **base,** somewhat triangular in shape, presents at the lateral and posterior part an oval or circular concave **articular surface** [facies articularis], directed medialward and downward to meet the arytænoid articular surface of the cricoid cartilage. The lateral angle of the base is prolonged into a stout **muscular process** [processus muscularis] for the attachment of the crico-arytænoid muscles, while the anterior angle is extended as a sharp projection, the **vocal process** [processus vocalis], which serves for the attachment of the vocal ligament. The surfaces of the arytænoid are named medial, posterior, and antero-lateral. The narrow **medial surface,** covered by the mucosa of the larynx, is nearly vertical, and faces the corresponding side of the opposite arytænoid, from which it is separated by a small space. The **posterior surface** is concave for muscular attachment. The **antero-lateral surface** is the largest, and presents an irregular contour.

On this surface a ridge, the **arcuate crest** [crista arcuata], extends horizontally between two hollows—the **triangular fovea** [fovea triangularis] above, which lodges some mucous glands, and a larger depression below, the **oblong fovea** [fovea oblonga] for the vocal muscle. The **colliculus** is a small eminence found upon the anterior margin and antero-lateral surface.

FIG. 974.—FRONT VIEW OF THE LARYNGEAL SKELETON. (Modified from Bourgery and Jacob.)



The corniculate cartilages (of Santorini) [cartilagines corniculatæ (Santorini*)] (figs. 973, 977).—This pair of small conical cartilages is set upon the bent apices of the arytænoids, continuing their curves backward and medialward.

The corniculate cartilage is not an independent structure in many lower animals, and its continuity with the arytænoid is sometimes met with in man where the two cartilages are normally developed in a continuous mass of tissue.

The **epiglottic cartilage** [cartilago epiglottica] (figs. 973, 977, 981, 987), unpaired, invested by mucosa behind and partly in front, thin and leaf-shaped, stands behind the root of the tongue and the body of the hyoid. It lies above the thyreoid cartilage, in front of the entrance of the larynx. The free upper margin is convex, or notched; the lower end tapers to a short stalk, the **petiole** of the epiglottis [petiolus epiglottidis], to which the thyreo-epiglottic ligament is attached.

The anterior surface is free above and covered by mucosa; in its lower part it is bound to the body of the hyoid, and is separated by a mass of fat from

* Santorini: Venetian anatomist. B. 1681, D. 1737.

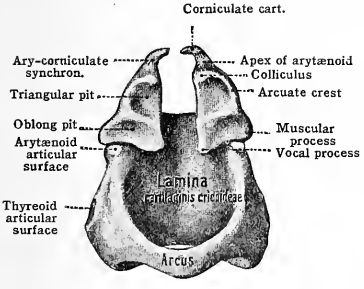
the hyo-thyreoid ligament. Its posterior surface above is saddle-shaped; below, it is convex, presenting the **epiglottic tubercle** [tuberculum epiglotticum]. To the margins are attached the ary-epiglottic folds. The epiglottic cartilage presents numerous small holes and depressions for the accommodation of glands.

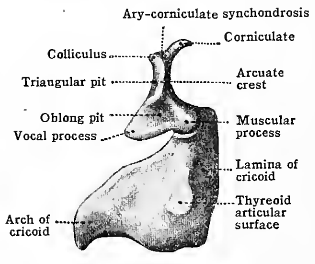
The **cuneiform cartilages (of Wrisberg)** [cartilagines cuneiformes (Wrisbergi*)] (fig. 973) lie as small, rod-like bodies in the ary-epiglottic folds anterior to the corniculate cartilages. They are variable in form and size and not rarely absent altogether.

These cartilages are parts of the epiglottic cartilage in some mammals where, as in man, they lie in the ary-epiglottic folds. Their relations to the arytænoids are regarded as secondary. Sutton has shown that in the ant-eater a continuous rim of yellow elastic cartilage extends from the sides of the epiglottic cartilage to the summits of the arytænoids. A minute unpaired *interarytænoid* or *procricoid cartilage* is rarely present imbedded in the cricopharyngeal ligament and covered by the pharyngeal mucosa. It is a constant structure in certain mammals. A pair of small *sesamoid cartilages*, also constantly present in some mammals, is occasionally found in man at the lateral margins of the arytænoids, connected with them and with the corniculate cartilages by elastic ligaments.

Structure of the cartilages.—The thyreoid, cricoid, and greater part of the arytænoid are composed of hyaline cartilage; the epiglottic, corniculate, and cuneiform cartilages, as well as the apex and vocal process of the arytænoid, are of elastic cartilage. Certain parts of the laryngeal skeleton normally undergo calcification and subsequent ossification. Calcification begins at about twenty years of age in the thyreoid and cricoid cartilages, and later in the arytænoid. The process begins a little later in the female than in the male, and does not extend so rapidly. The extent to which the cartilages are ossified and the time occupied in the process vary considerably. The elastic elements are not involved in the process.

Fig. 975.—Cricoid and Arytænoid Cartilages seen from Before. (Rauber-Kopsch.)
Fig. 976.—Cricoid and Arytænoid Cartilages seen from the Left. (Rauber-Kopsch.)





THE JOINTS AND FIBROUS MEMBRANES OF THE LARYNX

(1) Connections between the Laryngeal Cartilages

The crico-thyreoid articulation (figs. 973, 974, 975).—The articular surfaces concerned are the thyreoid articular surface on the side of the cricoid and the articular surface on the inferior cornu of the thyreoid cartilage. The **crico-thyreoid articular capsule** [capsula articularis cricothyreoidea] attached around the margins of these surfaces and certain accessory bands serve to bind the cartilages together.

The accessory bands, **cerato-cricoid ligaments** fall into three groups radiating from the inferior cornu: the **ligamenta ceratocricoidea posteriora** upward and medialward to the superior margin of the cricoid; the **ligamenta ceratocricoidea lateralia** downward at the side and back of the capsule; the **ligamentum ceratocricoideum anterius** downward and forward. The capsule possesses a synovial layer.

A rotary movement about a transverse axis of the cricoid upon the thyreoid or *vice versa* and a slight backward and forward gliding are permitted at this joint.

* Wrisberg: German anatomist. B. 1737, D. 1808.

The crico-arytænoid articulation [articulatio cricoarytænoidea (figs. 973, 977, 978).—The articular surface of the cricoid cartilage and the articular surface of the arytænoid which enter into this articulation are so disposed that at no time do they meet in complete apposition. A loose capsule [capsula articularis crico-

FIG. 977.—THE LARYNGEAL SKELETON SEEN FROM BEHIND. (Poirier and Charpy.)

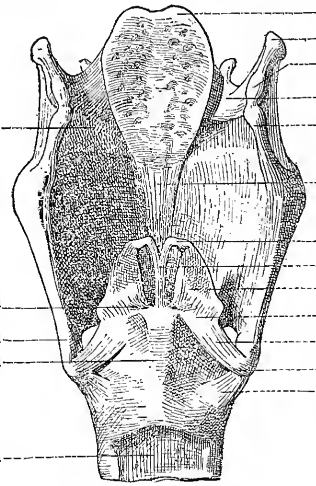


FIG. 978.—THE LARYNX WITH ITS LIGAMENTS, VIEWED FROM THE RIGHT. (The right lamina of the thyreoid cartilage has been removed.) (Spalteholz.)

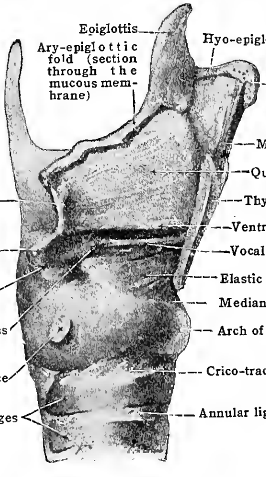


arytænoidea] of fibrous and synovial strata attached around the edges of the joint surfaces unites the cartilages.

Posterior crico-arytænoid ligament [lig. cricoarytænoideum posterius], attached above to the medial surface of the base and muscular process of the arytænoid, and below to the lamina of the cricoid, is important in helping to fix the former cartilage in place upon the sloping arytænoid articular surface of the cricoid and in limiting its movements. Motion at this articulation is very free. The following simple movements of the arytænoid are best understood:—(1) gliding of the arytænoid toward or away from its fellow; (2) inclining forward and backward; (3) rotating on a vertical axis, so that the vocal process sweeps medialward or lateralward and also a little downward or upward.

The union of the corniculate cartilage with the apex of the arytænoid cartilage [synchondrosis arycorniculata] is usually by connective tissue; rarely is there a joint cavity.

The petiole of the epiglottic cartilage is connected with the thyreoid, below and behind the superior notch, by a strong, elastic **thyreo-epiglottic ligament** [lig. thyreoepiglotticum] (fig. 977).

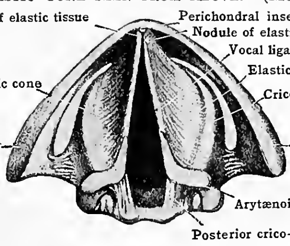
(2) The Elastic Membrane of the Larynx

[Membrana elastica laryngis]

This name is given to a more or less continuous sheet of elastic fibres connected with the deeper parts of the laryngeal mucosa. Its upper part is known as the *quadrangular membrane*, the lower part as the *elastic cone*. A middle region of the elastic membrane lies opposite the ventricle of the larynx.

The **quadrangular membrane** (figs. 978, 981, 988) extends from the ary-epiglottic folds above to the level of the ventricular folds (false vocal cords) below. The lateral parts of this membrane are widely separated superiorly, but they converge toward the middle line as they descend. Anteriorly, the membrane is fixed in the angle of the thyreoid laminæ and to the sides of the epiglottic cartilage; posteriorly, to the corniculate cartilages and to the arytænoids. The superior edge on either side lies within the ary-epiglottic fold, which it supports; it slopes downward and backward and includes the cuneiform cartilage. The inferior edge, horizontal and in a sagittal plane, is best developed in front, where it is attached in the angle of the thyreoid a little way from the middle line; behind, it is fixed to the medial margin of the triangular fovea of the arytænoid. This inferior free margin, differentiated as the **ventricular ligament** [lig. ventriculare], is enclosed within, and is the support for the ventricular fold.

Fig. 979.—The Elastic Cone seen from Above. (Modified from Luschka.)



The elastic cone [conus elasticus] (figs. 978, 979).—This part of the elastic membrane extends from the level of the vocal folds to the superior margin of the cricoid cartilage. Its component fibres are attached in the re-entrant angle and adjacent lower margin of the thyreoid cartilage, whence they spread downward and backward to the upper edge of the cricoid arch and to the arytænoid cartilages. The strong anterior portion, perforated by vessels, is the **median crico-thyreoid ligament** [lig. cricothyreoideum (medium)] (figs. 974, 975). The lateral parts (lateral portions of the crico-thyreoid membrane) present superior free edges, somewhat thickened, which, running horizontally near the middle line from the thyreoid angle to the vocal processes, constitute the **vocal ligaments**. These are inserted anteriorly into a perichondral process in the thyreoid angle; posteriorly, they have a wide area of attachment to the upper and medial surfaces of the vocal processes of the arytænoids with the elastic fibres of which they are in part continuous. A yellowish, cellular nodule (sometimes cartilage) occurs in the anterior end of each ligament. The vocal ligaments enter into the formation of the vocal folds (true vocal cords).

Fig. 980.—The Larynx seen from the Left Side. (Modified from Luschka.)

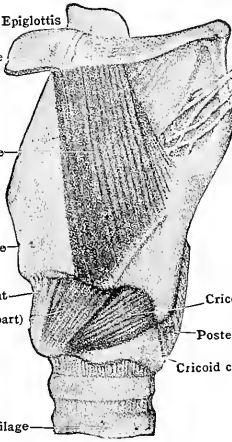


Fig. 981.—The Muscles and Ligaments of the Larynx seen from the Side. (The left lamina of the thyreoid cartilage has been removed.)

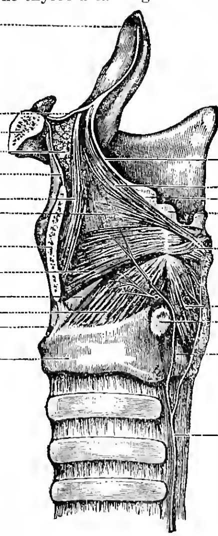

The median crico-thyreoid ligament is incised in the operation of laryngotomy. It is crossed by the anastomotic arch of the crico-thyreoid arteries, which, however, can be avoided in the operation by making a transverse cut through the ligament close to the superior margin of the arch of the cricoid cartilage.

(3) Connections between the Larynx and Neighbouring Structures

The **hyo-thyreoid membrane** [membrana hyothyreoidea] (figs. 977, 980, 981) is a loose, fibrous, elastic sheet, binding together the thyreoid cartilage and hyoid bone. It extends from the superior margin of the former to the greater cornua and superior margin of the body of the latter. The superior laryngeal artery and vein and the internal laryngeal nerve pass through it from the side. Its posterior and lateral edge is cord-like, consisting of elastic fibres which stretch as the **lateral hyo-thyreoid ligament** [lig. hyothyreoideum laterale] from the superior cornu of the thyreoid to the greater cornu of the hyoid. A small **cartilago triticea** is sometimes present in this band. The middle part, **median hyo-thyreoid ligament** [lig. hyothyreoideum medium] thick and elastic, extends from the superior thyreoid notch upward behind the body of the hyoid to be attached to its superior margin, the *hyoid bursa* being interposed between the bone and the membrane.

Fig. 982.—Scheme of Rima, showing Action of Posterior Crico-arytænoid Muscle, which draws the Arytænoid Cartilage from I to II. (Modified from Stirling.)

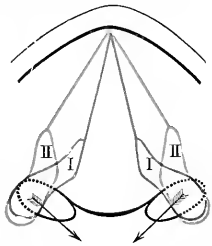

Fig. 983.—Scheme showing Action of the Transverse Arytænoid drawing Arytænoid Cartilage from Neutral Position I to II. (Modified from Stirling.)

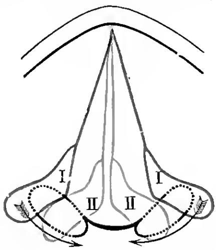

Fig. 984.—Scheme showing Action of Thyreo-artyænoid drawing the Vocal Processes and the Vocal Ligaments from II to I. (Modified from Stirling.)

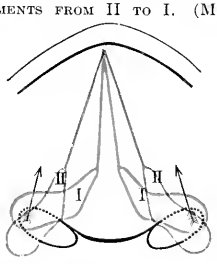


The cartilago triticea is the remains of a connection between the thyreoid and hyoid present in the embryo. It persists in adult life in some lower animals.

The **hyo-epiglottic ligament** [lig. hyoepiglotticum] (figs. 978, 981) connects the anterior surface of the epiglottic cartilage with the superior margin of the body and the greater cornua of the hyoid. It is a broad sheet, lying above a mass of fat which stands between the median hyo-thyreoid membrane and the epiglottis and spreading laterally to join the pharyngeal aponeurosis in the region of the piriform recess.

The name *glosso-epiglottic ligament* is given to the elastic fibres extending between the root of the tongue and the epiglottis within the median glosso-epiglottic fold.

The **corniculo-pharyngeal ligament** (fig. 977) extends from the corniculate cartilage downward and toward the median line, attaching to the mucosa of the pharynx and joining its fellow behind the arytænoid muscle. From this point a single band, the **crico-pharyngeal ligament** [lig. cricopharyngeum], which may enclose a nodule of cartilage (**the interarytænoid or procricoid cartilage**), descends in the middle line, to be fixed to the cricoid lamina and into the pharyngeal mucosa.

The larynx and trachea are united by fibrous membrane, the **crico-tracheal ligament** [lig. cricotracheale] (figs. 974, 978), between the inferior margin of the cricoid cartilage and the upper margin of the first tracheal ring. Posteriorly the ligament is continued into the membranous wall of the trachea.

MUSCLES OF THE LARYNX

Of the many muscles connected with the larynx, two groups may be recognised, the members of one coming from neighbouring parts, fixing themselves to the larynx and acting upon the organ as a whole; the members of the other group confining themselves exclusively to the larynx and acting so as to affect its parts. The muscles composing the first group are described elsewhere. (See Section IV.) The muscles of the second group are composed of striated fibres and are supplied by the vagus nerve through its laryngeal branches. These muscles are all more or less under cover of the thyreoid cartilage, with one exception, the crico-thyreoid.

The **crico-thyreoid muscles** [m. cricothyreoideus] (fig. 980) are placed one on either side of the outer surface of the larynx in its lower part. Each muscle is partially separated into an anterior **straight** [pars recta] and a posterior **oblique portion** [pars obliqua], which together arise from the arch of the cricoid. The fibres of the straight part ascend steeply and are inserted into the inferior margin of the thyreoid cartilage. The oblique portion is inserted into the inferior cornu and into the lower margin and inner surface of the thyreoid cartilage.

The straight part elevates the arch of the cricoid, causing the lamina, and with it the arytænoid cartilages, to sink, while the oblique part draws forward the thyreoid; thus the vocal ligaments are made tense. The muscle is supplied by the external branch of the superior laryngeal nerve. A connexion between the posterior part of this muscle and the inferior constrictor of the pharynx and their common nerve-supply indicate their genetic relationship.

The **posterior crico-arytænoid** muscle [m. cricoarytænoideus posterior] (figs. 980, 981, 982), paired, is situated at the back of the larynx, covered by the submucous coat of the pharynx. It is a thick, triangular mass which takes origin from the posterior surface of the cricoid lamina, the two muscles being well separated by the median crest of the cartilage. The lower fibres ascend and the upper ones pass horizontally lateralward and are inserted into the muscular process of the arytænoid cartilage on its posterior surface and tip.

When these muscles contract, the muscular processes of the arytænoids are pulled backward and downward, while the vocal processes travel lateralward and a little upward, so that the rima glottidis is widened and the vocal ligaments made tense (fig. 982). The innervation is by the posterior branch of the inferior laryngeal nerve.

In ether narcosis the dilator muscle is later paralyzed and afterward earlier restored than the constrictors of the larynx.

At the lower margin of this muscle a small slip, the **cerato-cricoid muscle** [m. ceratocricoideus], is sometimes found, extending between the lamina of the cricoid and the inferior cornu of the thyreoid cartilage.

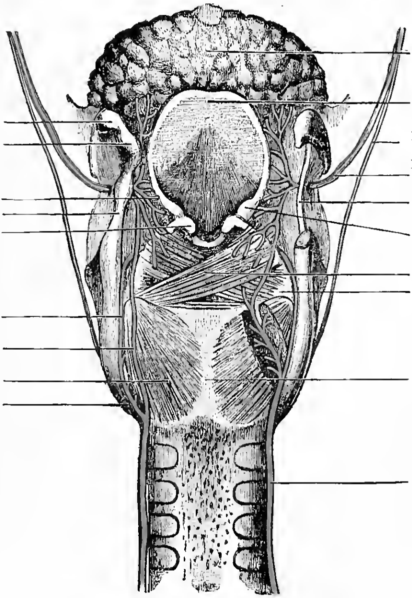
The constrictor laryngis.—Whereas the crico-arytænoideus posterior is a dilator of the larynx, the several muscles now to be considered are in the main constrictors. They form a ring, the constrictor laryngis, around the laryngeal cavity, interrupted, however, by the cartilages. In the larynx of amphibia and reptiles a complete sphincter guards the entrance to the air-passages.

The following muscles are included in the constrictor group:—

The **transverse arytænoid** muscle [m. arytænoideus transversus] (figs. 981) 983, 985) is a single muscle of quadrilateral form, extending across the middle line from the posterior concave surface of one arytænoid cartilage to that of the other. Its anterior surface, between the cartilages, is covered by the laryngeal mucosa; its posterior surface, crossed by the arytænoideus obliquus, is clothed by the submucous coat of the pharynx.

The arytænoideus transversus approximates the arytænoid cartilages and their vocal processes, which are at the same time elevated, and the vocal ligaments made tense. It is supplied by the posterior branch of the inferior laryngeal nerve.

Fig. 985.—The Nerves of the Larynx seen from Behind.



The **lateral crico-arytænoid** muscle [m. cricoarytænoideus lateralis] (fig. 981) arises from the upper margin and outer surface of the cricoid arch and from the elastic cone, whence the fibres extend backward and upward to an insertion on the anterior surface of the muscular process of the arytænoid cartilage. This muscle is inseparable from the thyreo-arytænoideus in about half the cases.

The lateral cricoarytænoids by their contraction cause the vocal processes to move toward the median line and a little downward, so that the vocal ligaments are approximated and slightly stretched. They antagonise the posterior crico-arytænoids. The anterior branch of the inferior laryngeal nerve supplies these muscles.

The **external thyreo-arytænoid** muscle [m. thyreoarytænoideus (externus)] (figs. 981, 984, 988), variable in form and in the disposition of its fibres, is closely connected with the preceding. It lies under cover of the thyreoid lamina lateral to the laryngeal saccule (ventricular appendix) and elastic cone. Arising within the angle of the thyreoid laminæ the muscle extends upward and backward to its insertion on the lateral margin of the arytænoid cartilage.

It draws forward the arytænoid cartilage (and also tilts the cricoid), and rotates it so that the vocal process passes medialward and downward, relaxing the vocal ligament. It is the antagonist of the crico-thyreoid (fig. 984). Its nerve-supply is the anterior branch of the inferior laryngeal.

The **vocal muscle** [m. vocalis], (fig. 988), prismatic in form, is the inner constant part of the thyreo-arytænoideus. It lies in the vocal lip lateral to the vocal ligament. Its fibres run from their origin in the angle of the thyreoid laminæ to their insertion in the vocal process and oblong fovea of the arytænoid cartilage.

It draws forward the vocal process, relaxing the vocal ligament. Its nerve comes from the anterior branch of the inferior laryngeal.

The insertion of certain fibres of this muscle into the elastic vocal ligament has been observed (ary-vocalis muscle of Ludwig). D. Lewis has shown that some of the elastic fibres in the vocal ligament are derived from the perimysium of the vocal muscle.

The **ventricular muscle** [m. ventricularis] consists of a few fibres derived from the thyreo-arytænoideus which reach the back of the laryngeal saccule and enter the ventricular fold. The small *thyreo-arytænoideus superior* extends from the angle of the thyreoid to the muscular process of the arytænoid upon the lateral surface of the main muscle.

The **oblique arytænoid** muscle [m. arytænoideus obliquus] is a slender band lying at the back of the larynx and under the pharyngeal submucosa. It arises from the muscular process of the arytænoid posteriorly, and, ascending obliquely, crosses its fellow in the median line. Some fibres are inserted into the apex of the opposite arytænoid cartilage; other fibres sweep around the apex and accompany the thyreo-arytænoid to an insertion in the angle of the thyreoid cartilage, constituting the *thyreo-arytænoideus obliquus.*

This muscle contracts the laryngeal aperture and vestibule of the larynx. Its nerve is derived from the anterior branch of the inferior laryngeal.

Closely connected with the thyreo-arytænoideus is a bundle of fibres of fairly regular occurrence, called the **thyreo-epiglottic muscle** [m. thyreoepiglotticus] (fig. 981). It originates from the inner surface of the thyreoid lamina and proceeds upward and backward to end in the quadrangular membrane and to become attached to the lateral border of the epiglottis.

The *ary-membranosus* and *ary-epiglottic muscles* are inconstant fascicles of the constrictor group which run in the ary-epiglottic fold and become fixed into the quadrangular membrane and margin of the epiglottic cartilage.

Summary of the Actions of the Laryngeal Muscles

According to their actions, the laryngeal muscles may be divided into—(*a*) those which effect the tension of the vocal folds; (*b*) those which control the rima glottidis; (*c*) those which effect the closure of the laryngeal aperture and vestibule.

(*a*) The vocal ligaments are made tense by the action of the crico-thyreoid, the lateral and posterior cricoarytænoid and the transverse arytænoid muscles. The vocal ligaments are relaxed as the result of the action of the external thyreo-arytænoid and vocal muscles.

(*b*) The rima glottidis is widened by the crico-arytænoideus posterior and made narrow by the contraction of the arytænoids. The crico-arytænoideus lateralis also assists in closing the rima glottidis by rotating the vocal processes medialward, and if the crico-arytænoideus posterior contracts simultaneously, it aids in the closure. The vocal ligaments are approximated also by the thyreo-arytænoideus [externus].

(*c*) The laryngeal aperture and vestibule are closed mainly by the arytænoideus transversus and thyreo-arytænoideus (externus), by which the arytænoid cartilages are brought into apposition and drawn toward the epiglottis. Other muscles derived from the constrictor group, arytænoideus obliquus and ary-epiglotticus assist in closing the laryngeal aperture.

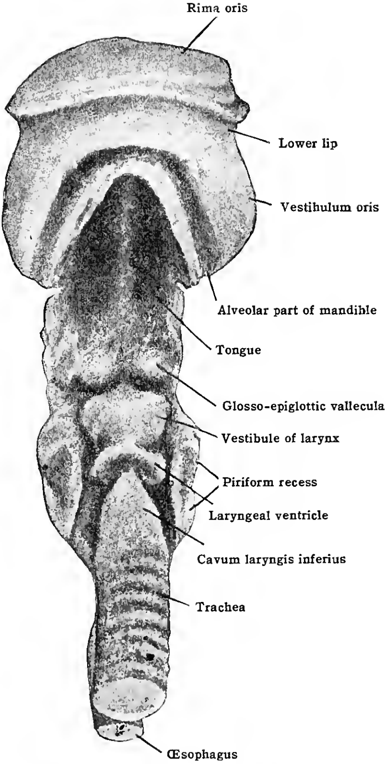
CAVITY OF THE LARYNX AND LARYNGEAL MUCOSA

The **cavity of the larynx** [cavum laryngis] is relatively narrow and does not correspond in shape with the outer surface of the organ. Its form is shown in fig. 986 taken from a cast of the laryngeal cavity and the spaces continuous with it. Its walls are covered throughout by the **mucous membrane** of the larynx (figs. 987, 988).

The mucosa of the larynx is continuous above with the mucous membrane of the pharynx, below with that of the trachea (figs. 970, 971). At the root of the tongue the pharyngeal mucosa is reflected backward to the anterior surface of the epiglottis, presenting the **median** and **lateral glosso-epiglottic folds** [plica glosso epiglottica medianaet lateralis]. From the sides of the pharynx it passes medialward, first sinking between the thyreoid cartilage laterally and the arytænoid and cricoid medially, entering into the walls of the piriform recess; then passing over the superior margin of the quadrangular membrane to form the ary-epiglottic fold.

At the medial side of the piriform recess a slight fold of the mucosa [plica nervi laryngei) corresponds to the superior laryngeal nerve. Between the root of the tongue and the epiglottis is a depression subdivided in the middle line and limited laterally by the median and lateral

Fig. 986.—Cast of the Vestibulum and Cavum Oris, of the Pharynx, Larynx, of the Upper Part of the Trachea and Œsophagus. Seen from in front and below. (Rauber-Kopsch.)

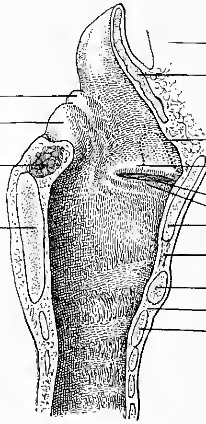


glosso-epiglottic folds; this is the **epiglottic vallecula** [vallecula epiglottica]. The piriform recess and the epiglottic vallecula are favorite sites for the lodgment of foreign bodies. The **ary-epiglottic fold** [plica aryepiglottica] extends from the side of the epiglottis to the apex of the arytænoid cartilage; within it are fibres of the ary-epiglottic and thyreo-epiglottic muscles and the cuneiform and corniculate cartilages. These cartilages correspond to two rounded eminences on each side of the laryngeal entrance, the **cuneiform** and **corniculate tubercles** [tuberculum cuneiforme (Wrisbergi); tuberculum corniculatum (Santorini)], respectively. Of these, the former is often small and inconspicuous, the latter usually well developed and prominent.

The cavity of the larynx above the level of the ventricular folds is known as the **vestibule** [vestibulum laryngis]. This is wide in its upper part, but the sides incline toward the median line in descending, and the cavity becomes narrow transversely in approaching the region of the glottis. Here the cavity has received the special name, **superior entrance to the glottis** [aditus glottidis superior]. The parts of the framework of the larynx which enter into the walls of the vestibule are: in front, the epiglottic and thyreoid cartilages with the thyreo-epiglottic ligament; at the side, the quadrangular membrane, the cuneiform and corniculate cartilages, and the medial surface of the arytænoid cartilage; behind, the anterior surface of the transverse arytænoid muscle. The vestibule communicates with the pharynx by the **laryngeal aperture** [aditus laryngis] (figs. 970, 971, 972, 987), which looks upward and backward. The form of the aperture is oval or triangular, with the base in front; here it is bounded by the epiglottis; laterally by the ary-epiglottic fold of the mucosa. Posteriorly the laryngeal aperture is prolonged as a little notch between the corniculate cartilages and the apices of the arytænoids [**incisura interarytænoidea**] limited behind by a commissure of the mucosa.

The high anterior wall of the vestibule presents a marked convexity, the **tubercle of the epiglottis** [tuberculum epiglotticum], over the thyreo-epiglottic ligament. The lateral walls,

Fig. 987.—Median Section of the Larynx. (Merkel.)



higher in front than behind, show two slight ridges, separated by a shallow groove, extending downward from the cuneiform and corniculate tubercles. The posterior wall, very low, corresponds to the commissure connecting the arytænoid cartilages.

On either side of the vestibule, toward its inferior end, is the sagittally running **ventricular fold** [plica ventricularis] (false vocal cord) (figs. 970, 971, 987, 988). This appears as an elevation of the mucous coat of the lateral wall, prominent in its middle and anteriorly, fading away posteriorly. The ventricular fold contains the inferior free edge of the quadrangular membrane, that is, the ventricular ligament, and numerous glands.

Wylie's experiments with the ventricular folds led him to conclude that the closure of the glottis in defæcation and vomiting is mainly effected by the apposition of these folds. (Quain.)

The interval between the right and left ventricular folds, the **vestibular slit** [rima vestibuli] leads downward to a space between the planes of the ventricular and vocal folds, which extends on each side into the **laryngeal ventricle** [ventriculus laryngis (Morgagni*)] (figs. 970, 971, 987, 988). The latter is a little antero-posterior pocket of the mucosa reaching from the level of the arytænoid nearly to the angle of the thyreoid cartilage, and undermining the ventricular fold; it opens into the cavity of the larynx by a narrow mouth limited above and below by the ventricular and vocal folds. From its anterior part a small diverticulum,

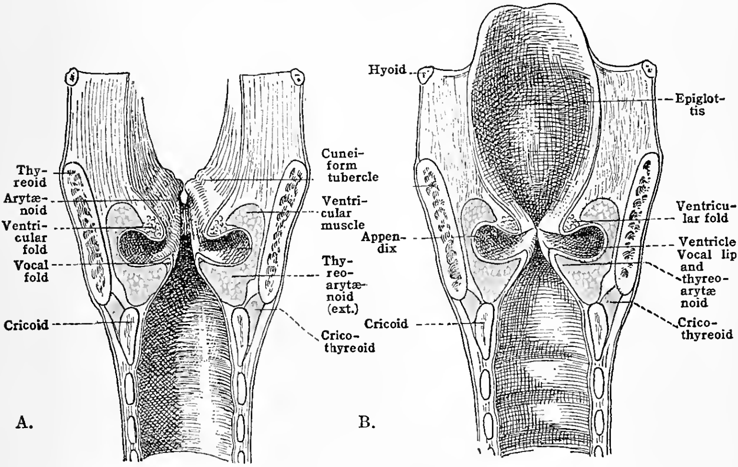
* Morgagni. Italian anatomist. B. 1682, D. 1771.

the **ventricular appendix** [appendix ventriculi laryngis] extends upward between the ventricular fold medially and the thyreo-arytænoid muscle and thyreoid cartilage laterally. Many mucous glands open into it.

The appendix is occasionally so large as to reach the level of the upper margin of the thyreoid cartilage or even the great cornu of the hyoid bone. The laryngeal pouches of some of the apes are remarkably developed and appear to serve in affecting the resonance of the voice. In man, their function, besides that of pouring out the secretion of the glands located within their walls, is not known.

The **vocal fold** [plica vocalis] (or true vocal cord) (figs. 970, 971, 987, 988) is the thin edge of a full, lip-like projection, the vocal lip. The vocal folds correspond in antero-posterior extent to the vocal ligament, and stand nearer the median line than the ventricular fold. In colour the vocal folds are pearly white, excepting the anterior end of each, where there is a **yellow spot** [macula flava] produced by a little mass of elastic tissue (sometimes cartilage) in the ligament, The **vocal lip** [labium vocale] forms the floor of the ventricle and contains the upper part of the elastic cone, whose thickened free edge, the vocal ligament, lies in the

Fig. 988.—Frontal Section of a Larynx Hardened in Alcohol. A. Posterior segment. B. Anterior segment. (Poirier and Charpy.)



vocal fold and along the vocal muscle. The two vocal lips with the vocal folds and the intervening space, the rima glottidis, together constitute the sound-producing apparatus, the **glottis**.

Below the vocal folds and the medial surfaces of the arytænoid cartilages is a slit, the **rima glottidis** (figs. 970, 971, 988), the narrowest part of the laryngeal cavity, extending from the arytænoideus transversus muscle posteriorly to the thyreoid cartilage in front. The portion of the rima between the vocal folds is known as the **pars intermembranacea;** that between the arytænoids the **pars intercartilaginea.** The rima glottidis in easy respiration is narrow and has the form of a long triangle; in laboured breathing it is widely open and lozenge-shaped.

Below the level of the vocal folds is the space called the **inferior entrance to the glottis** [aditus glottidis inferior] (fig. 988), which is narrow from side to side above, wide and circular in section below—altogether somewhat funnel-shaped. Its walls are formed by the elastic cone and by the arch and lamina of the cricoid cartilage. The lining mucosa is separated from the elastic cone by numerous glands and loose connective tissue, a condition favorable to the development of œdema; below it is continuous with the mucosa of the trachea.

By means of the laryngoscope a more or less complete picture of the laryngeal aperture and the cavity of the larynx can be obtained (figs. 970, 971). There appear, highest up, the root of the tongue with the epiglottic valleculæ and glosso-epiglottic folds leading backward to the epiglottis; behind the latter, the triangular aperture of the larynx, bounded at the sides by the ary-epiglottic folds. Further lateralward appear the piriform recesses, the laryngeal portions of which lie as transverse fissures behind the laryngeal aperture. Within the ary-epiglottic folds are seen the prominent corniculate tubercles on either side of the inter-arytænoid commissure and just anterior, the variable cuneiform tubercles. Within the vestibule the epiglottic tubercle rises upon the anterior wall, while at the sides appear the ventricular folds overhanging the slit-like openings of the laryngeal ventricles. Below this level the vocal folds stand out on either side approaching nearer the median plane than do the ventricular folds and conspicuous by their pearly whiteness. The form and extent of the rima glottidis and of its divisions, the intermembranous and intercartilaginous parts, can be inspected. Far down, the cricoid cartilage and anterior wall of the trachea may appear and under favourable conditions a glimpse of the bifurcation of the latter can be obtained.

The **mucous coat of the larynx** [tunica mucosa laryngis] in general is covered by a ciliated epithelium; the vocal lips, and, exceptionally, small areas of the mucosa of the laryngeal surface of the epiglottis and the ventricular folds possess a covering of flat, non-ciliated cells. The attachment of the mucosa to the underlying parts is very firm about the vocal folds and dorsal side of the epiglottis, and loose in the ary-epiglottic folds, where much areolar tissue is present. In general the mucosa is pink in colour, becoming bright red over the epiglottic tubercle and edges of the epiglottis and fading over the vocal folds, which appear almost white.

Numerous **mucous glands** [glandulæ laryngeæ] occur about the larynx and are aggregated into groups in certain places. One cluster of **anterior glands** [gl. laryngeæ anteriores] is found in front of and on the posterior side of the epiglottis; another, the **middle glands** [gl. laryngeæ mediæ], is in the ventricular fold, in the triangular fovea of the arytænoid cartilage and clustered about the cuneiform cartilage, while a third set, the **posterior glands** [gl. laryngeæ posteriores], is disposed about the transverse arytænoid muscle. Many glands pour their secretion into the appendix of the laryngeal ventricle, but there are none on or about the vocal folds. **Lymph-nodules** of the larynx [noduli lymphatici laryngei] occur in the mucosa of the ventricle and on the posterior surface of the epiglottis.

Position and relations.—The larynx opens above into the pharynx by the aditu and in thiss region is connected with the hyoid bone. Below, its cavity leads into the trachea. Its position in the neck is indicated on the surface by the laryngeal prominence (Adam's apple). It stands in front of the fourth, fifth, sixth, and seventh cervical vertebræ; from these it is separated by the prevertebral muscles and the pharynx, into the anterior wall of which it enters. The integument and cervical fascia cover the larynx anteriorly in the middle line, while toward the side are the sterno-hyoid, sterno-thryeoid, and thyreo-hyoid muscles. The lateral lobe of the thyreoid gland and the inferior constrictor of the pharynx are in relation to it laterally, while further removed are the great vessels and nerves of the neck.

Peculiarities of age and sex. Position.—The larynx is placed high in the neck in fœtal and infantile life and descends in later life. In a six-months fœtus the organ is two vertebræ higher than in the adult. (Symington.) The descent of the larynx has been attributed to the vertical growth of the facial part of the skull, but this cause is questioned by Cunningham, who points out the high position of the larynx in the anthropoid apes, where the facial growth is more striking than in man; it appears also that the larynx follows the thoracic viscera in their subsidence, which, according to Mehnert, continues until old age. At birth the interval between the hyoid bone and thyreoid cartilage is relatively very small and increases but little during early life.

Growth and form.—The larynx of the new-born is relatively large and in contour more rounded than that of the adult. The organ continues to grow until the third year, when a resting period begins, lasting until about twelve years of age, during which time there appears to be no difference between the larynx of the male and that of the female. At puberty, while no marked change is observable in the larynx of the female, rapid growth accompanied by modification of form of the larynx is initiated in the male. The laryngeal cavity is enlarged, the antero-posterior diameter markedly increased; the whole framework becomes stronger; the thyreoid cartilage especially increases greatly in its dimensions, giving rise to the laryngeal prominence; the vocal folds are lengthened and thickened, the voice changing in quality and pitch. These changes are, for the most part, effected in about two years, but complete development is not attained before twenty to twenty-five years of age. Castration is known to influence the development of the larynx, for in the eunuch it has been found to resemble that of a young woman. The changes in the structure of the cartilages have already been described.

Dimensions.—In the male the distance from the upper edge of the epiglottis to the lower margin of the cricoid is 70 mm.; in the female, 48 mm. The transverse diameter is 40 mm. in the male, 35 mm. in the female. The greatest sagittal diameter is 40 mm. in the male, 37 mm. in the female. The vocal folds in the male measure relaxed about 15 mm., in the female, but 11 mm.; when stretched, about 20 mm. and 15 mm. respectively.

The length of the rima glottidis in the quiescent state is on the average 23 mm. in the male; 17 mm. in the female. In the male the pars intermembranacea measures 15.5 mm., the pars intercartilaginea, 7.5 mm. In the female these are 11.5 mm. and 5.5 mm. respectively. The rima may be lengthened by stretching of the vocal folds to 27.5 mm. in the male and 20 mm. in the female. (Moura.) In the male the width of the rima glottidis is 6–8 mm. in its widest part, but may be increased nearly to 12 mm.

Vessels and nerves (figs. 980, 985).—The *arteries* supplying the larynx are the superior and inferior laryngeal, which accompany the internal and inferior laryngeal nerves respectively, and the crico-thyreoid arteries (see pp. 538, 564).

The superior and inferior laryngeal *veins* join the superior and inferior thyreoid veins respectively.

The *lymph* vascular system is well developed throughout the larynx generally, but in the vocal folds where the mucosa is thin and tightly bound down the vessels are scarce and small in size (see p. 719).

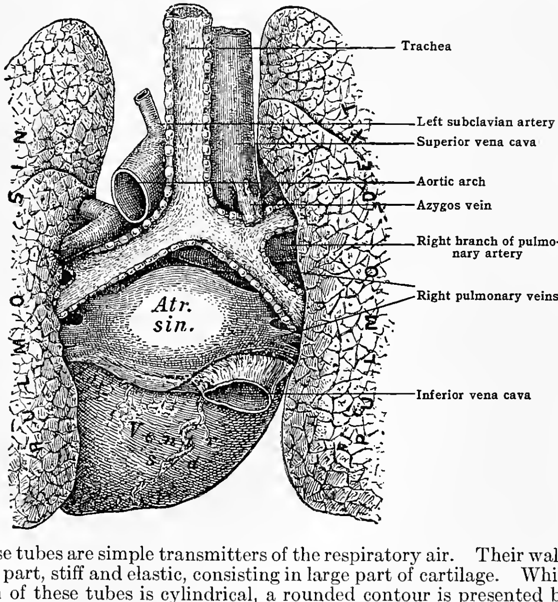
The *nerves* of the larynx are the superior and inferior laryngeal branches of the vagus and also certain branches of the sympathetic. Taste-buds occur and are abundant in the mucosa of the posterior surface of the epiglottis. The innervation of the muscles has already been indicated, and the description of the course and relations of these nerves will be found in the chapter on the Peripheral Nervous System. It should be mentioned here, however, that the idea of sharply limited territories of innervation, not only for the mucosa, but for the muscles as well, has been brought into question by the researches of Semon and Horsley, Exner, and others, which show that the distribution and functions of the laryngeal nerves are extremely complex.

The development of the larynx.—The larynx is developed partly from the lower portion of the embryonic pharynx and partly from the upper portion of the trachea. The cricoid cartilage represents the uppermost tracheal cartilage, while the thyreoid is formed by the fusion of four cartilages representing the ventral portions of the cartilages of the fourth and fifth branchial arches. The laryngeal muscles are derived from the musculature of these arches and consequently their nerve-supply is from the vagus. Whether or not the arytænoid and epiglottic cartilages are also derivatives of the branchial arches is uncertain, although it seems probable that they are.

THE TRACHEA AND BRONCHI

The tubular **trachea** (figs. 972, 989), or windpipe, extends from the larynx downward through the neck and into the thorax to end by dividing into two branches, the **right** and **left bronchi** [bronchus (dexter et sinister)], which lead to

Fig. 989—Trachea and Bronchi in Their Relations to the Great Vessels as seen from Behind. (After Gegenbaur.)

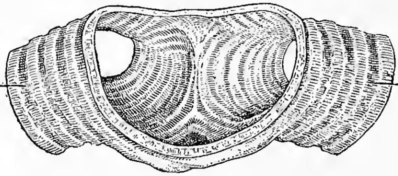


the lungs. These tubes are simple transmitters of the respiratory air. Their walls are, for the most part, stiff and elastic, consisting in large part of cartilage. While the general form of these tubes is cylindrical, a rounded contour is presented by their walls only in front and at the sides, the posterior surface being flat. The inner surface of the walls of the tubes presents a succession of slight annular projections caused by the cartilaginous rings which enter into their structure. The calibre of the trachea varies at different levels, a cast of the lumen being in general spindle-shaped. Its sectional area is less than the combined sectional areas of the two bronchi. When the **bifurcation** of the trachea [bifurcatio tracheæ] is viewed by looking down into its cavity, a sagitally directed keel, the carina tracheæ (fig. 990), is seen standing between the openings which lead into the bronchi. Its position is a little to the left of the mid-plane of the trachea in a slight majority of cases, or in the mid-plane in a large percentage.

Position and relations (figs. 972, 989, 1000).—The trachea lies in the median plane, extending from the level of the sixth cervical vertebra downward and backward, receding from the surface in following the curve of the vertebral column, and deviating a little to the right in approaching the level of the fourth thoracic vertebra, where it divides. Its lower end is fixed so that with elevation and descent of the larynx the tube is stretched and contracted, changes in length which also result from extension and flexion of the head and neck. The mobility of the trachea is favored by its loose investment of connective tissue.

About half of the trachea lies in the neck, but the extent varies with the length of the neck, the position of the head and with age; the trachea holds a lower position in adult life than in childhood and a still lower one in old age when the bifurcation may be as low as the sixth or seventh thoracic vertebra. In front and closely connected with it is the isthmus of the thyreoid gland, covering usually the second to fourth cartilages; anterior to this the cervical fascia and integuments. The cervical aponeurosis is attached to the upper margin of the sternum in two lamellæ, with an interspace containing the venous jugular arch, a lymph gland, and some fat. Between these aponeuroses and the trachea is another space containing the inferior thyreoid veins and some tracheal lymph-glands, and sometimes a thyreoidea ima artery. The innominate artery occasionally crosses the trachea obliquely in the root of the neck. Behind the trachea, in its whole length, lies the œsophagus, which in this part of its course inclines to the left. On either side are the great vessels and nerves of the neck, and the lobes of the thyreoid gland. The inferior laryngeal nerve lies in the angle between the œsophagus and trachea.

Fig. 990.—Bifurcation of the Trachea showing the Tracheal Keel. R. L. Right and left bronchi. (Heller and von Schroetter, from Poirier and Charpy.)



Within the thorax the trachea lies in the mediastinum, enveloped in loose areolar tissue and fixed through strong fibrous connections with the central tendon of the diaphragm. The innominate artery and the left common carotid are at first in front and then at its sides as they ascend, while the left innominate vein and the remains of the thymus are further forward. The aortic arch is in contact with the anterior surface of the trachea near the bifurcation. On the right side are the vagus nerve, the arch of the vena azygos, the superior vena cava, and the mediastinal pleura; on the left, the arch of the aorta, the left subclavian artery, and the recurrent laryngeal nerve. A large group of **bronchial lymph-glands** [lymphoglandulæ bronchiales] lies below the angle of bifurcation. The œsophagus is behind and to the left.

The **bronchi** take an oblique course to the hilus of the lung, where they branch. The right bronchus is nearer to the vertical in its course than is the left; it is also shorter and broader. These conditions, together with the position of the tracheal keel, explain the more frequent entrance of foreign bodies into the right than into the left bronchus. The asymmetrical course of the two bronchi is probably genetically associated with the position of the heart and aorta.

The azygos vein arches over the right bronchus, the vagus passes behind, and the right branch of the pulmonary artery crosses anteriorly below the level of the first (eparterial) branch of the bronchus. The aorta arches over the left bronchus and gains its posterior surface along with the œsophagus; the left branch of the pulmonary artery passes at first in front and then above the bronchus.

Dimensions.—On account of their elasticity considerable difficulty is met with in obtaining accurate measurements of the air-tubes. The length of the trachea is given at 95–122 mm.; its transverse diameter 20–27 mm.; the sagittal diameter 16–20 mm. The right bronchus has a length of 25–34 mm.; the left, 41–47 mm. The transverse diameter of the right is 18 mm.; of the left, 16 mm. The angle of bifurcation of the trachea varies from 56° to 90°, the mean being 70.4° a wide angle corresponding to the breadth of the thorax of man. The right bronchus makes an angle of 24.8° with the median plane; the left, 45.6°.

According to Tillaux the length of that portion of the trachea between the superior edge of the sternum and the cricoid cartilage varies with age and sex as follows:—

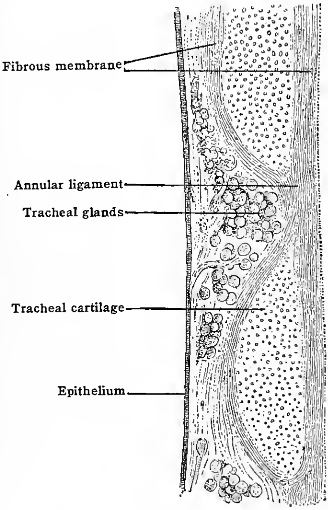
Adult male,	from 4.5 to 8.5 cm.	average, 6.5 cm.
Adult female,	" 5 to 7.5 cm.	" 6.4 cm.
Boys $2\frac{1}{2}$ to 10 years,	" 2.7 to 6.5 cm.	" 4.4 cm.
Girls $3\frac{1}{2}$ to $10\frac{1}{2}$ "	" 4 to 6.5 cm.	" 5.1 cm.

The diameter of the lumen of the trachea when distended to a cylindrical form has been measured by Sée:—

New-born	4.12 to 5.6 mm.
Infant 2 years	7.5 to 8 mm.
Infant 4 to 7	8 to 10.5 mm.
Over 20 years, male	16 to 22.5 mm.
Over 20 years, female	13 to 16 mm.

Structure of the trachea and bronchi (figs. 978, 988, 989, 991).—The walls of the trachea and bronchi are composed of a series of cartilages having the form of incomplete rings, held together and enclosed by a strong and elastic fibrous membrane. Posteriorly, where the rings are deficient, this membrane remains as the **membranous wall** [paries membranacea]; between the cartilages it constitutes the **annular ligaments** [ligg. annularia (trachealia)].

FIG. 991.—SCHEMATIC LONGITUDINAL SECTION OF THE WALL OF THE TRACHEA. (Gegenbaur.)



A **tracheal cartilage** [cartilago trachealis] comprises a little more than two-thirds of a circle. Its ends are rounded, its outer surface flat, while the inner surface is convex from above downward; the upper and lower margins are nearly parallel. The cartilages are from sixteen to twenty in number. The first is usually broader than the type, and is connected by the crico-tracheal ligament with the cricoid cartilage. Sometimes these two cartilages are in part continuous. The last cartilage is adapted to the bifurcation of the trachea and presents at the middle of its lower margin a hook-like process. This turns backward between the origins of the bronchi, and in the majority of cases gives a cartilaginous basis to the tracheal carina. Some of the tracheal cartilages vary from the type by bifurcating at one end. The cartilages keep the lumen of the trachea patent for the free passage of the air. Calcification occurs as with the laryngeal cartilages, but much later in life.

A **mucous coat** [tunica mucosa], soft and pinkish-white in colour, covers the inner surface of the trachea; posteriorly it is thrown into longitudinal folds. Mucous secreting **tracheal glands** [gl. tracheales] are present in the elastic **submucous coat** [tela submucosa] between the cartilages and at the back of the trachea. A thin layer of transversely disposed smooth muscle-fibres, stretching between the ends of the cartilages in the posterior wall, constitutes the **muscular**

coat [tunica muscularis]. Contraction of this trachealis muscle, as it is more properly named, causes the ends of the tracheal cartilages to be approximated and the lumen of the wind-pipe to be diminished.

The structure of the walls of the bronchi is similar to that of the trachea. The right bronchus possesses six to eight cartilages; the left, nine to twelve.

An inconstant *broncho-œsophageal* muscle may connect the back of the left bronchus with the gullet.

Vessels and nerves.—The *arteries* supplying these air-tubes come from the inferior thyreoid and from the internal mammary by its anterior mediastinal or bronchial branches. *Venous radicles* come together in the annular ligaments and join lateral veins on either side, which empty the blood into the plexuses of the neighbouring thyreoid veins.

Lymph-vessels are abundant, and are disposed in two sets, one in the mucosa, another in the submucosa. They drain into the tracheal, bronchial and œsophageal lymph-glands. *Nerves* are provided by the vagus direct, by the inferior laryngeal, and by the sympathetic.

THE LUNGS

The **lungs** [pulmones], the essential organs of respiration, are constructed in such a way as to permit the blood to come into close relation with the air (fig. 992). Their genetic connection with the entodermal canal has already been indicated (see also p. 1099). In plan of structure the lung has been compared with

a gland, since it is composed of a tree-like system of tubes terminating in expanded spaces. Closely associated with the system of tubes are certain blood-vessels, some of which take part in nourishing the organ, others participate in its special mechanism.

The lungs are two in number, and lie one on either side of the thoracic cavity, separated by a partition known as the **mediastinum** (figs. 993, 997, 1000). Serous membranes covering the latter right and left are parts of two closed sacs, the **pleuræ,** each of which is reflected about a lung and the neighbouring chest-wall after the manner of serous membranes in general. The space enclosed within the sac-walls is the **pleural cavity,** genetically a subdivision of the cœlom.

Form (figs. 994, 998).—The lung is pyramidal or conical in form, with the **base** [basis pulmonis] below and resting on the diaphragm, and with **apex** [apex pulmonis] above, in the root of the neck. Two surfaces, costal and mediastinal, are described. The broad convex **costal surface** [facies costalis] is directed against the thoracic wall in front, laterally and behind, and is marked by grooves corresponding to the ribs. The **mediastinal surface** [facies mediastinalis] is concave and presents a contour adapted to structures of the mediastinum (fig. 994). A special concavity on this surface, known as the *cardiac fossa*, corresponds to the prominence of the heart and is deeper in the left lung than in the right. Above and behind the cardiac fossa is a depression, the **hilus** of the lung [hilus pulmonis], where the bronchus and pulmonary vessels and nerves together constituting the **root** of the lung [radix pulmonis], enter and leave. Near the posterior edge of the mediastinal surface is a groove, which ascends and turns forward over the hilus; the groove of the left lung is adapted to the cylindrical surface of the aorta; that of the right, the vena azygos. A well-marked **subclavian sulcus** [sulcus sub-

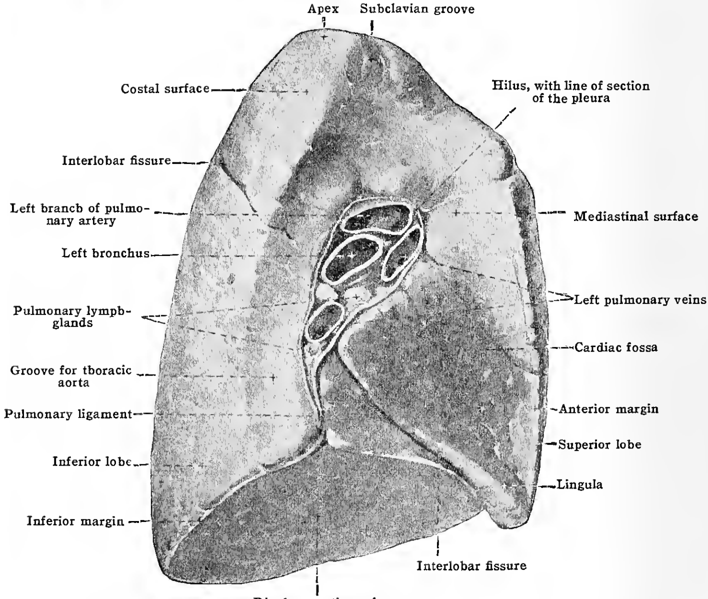
clavius] extends upward on this surface to the apex, corresponding on the right side to the lower part of the trachea and right subclavian artery, on the left to the left subclavian artery alone. Further forward is a groove adapted in the right lung to the superior cava; in the left to the left innominate vein. The lung is not in actual contact with these several structures, but is separated from them by the mediastinal pleura. The mediastinal surface passes gradually into the costal surface posteriorly, there being no proper posterior edge. Where the mediastinal and costal surfaces meet in front, a sharp **anterior margin** [margo anterior] exists (fig. 997). In the right lung this runs down in a gentle curve to turn lateralward in the inferior margin. In the left lung the anterior margin is cut into by a wide **cardiac notch** [incisura cardiaca], which is occupied by the heart in the pericardium as it is pressed toward the anterior thoracic wall. The cardiac notch is separated from the inferior margin by a little tongue of lung substance, the pulmonary **lingula** [lingula pulmonis].

The **base** of the lung (fig. 994) presents the **diaphragmatic surface** [facies diaphragmatica] concave and oblique in adaptation to the dome of the diaphragm. It is limited by a sharp **inferior margin** [margo inferior], which follows the curves of the mediastinal and costal surfaces, and fits into the angle between the diaphragm and thoracic wall.

The **apex** (figs. 994, 997, 998) is rounded and points upward with an inclination forward and medially, accommodating itself to the structures within and about the superior aperture of the thorax.

A deep **interlobar fissure** [incisura interlobaris] (figs. 994, 998), reaching through the lung substance nearly to the hilus, divides each organ into a smaller **superior lobe** [lobus superior] and a larger **inferior lobe** [lobus inferior]. The interlobar fissure runs downward and forward beginning a short distance below the apex, and reaching the base near the anterior margin in the left lung, somewhat further back in the right lung. From the obliquity of the plane of the fissure it will be noticed that the inferior lobe reaches posteriorly to within a short distance of the apex, and includes the greater part of the back and base of the lung, while the superior lobe takes in the anterior margin and apex. The presence of a **middle lobe** [lobus medius] disturbs the symmetry of the right lung. This results from a deep, nearly horizontal incisure cutting through the lung somewhat below its middle, and extending between the anterior margin and the main interlobar fissure, which it reaches at about the level of the axillary line.

Fig. 994.—Left Lung, viewed from the Mediastinal Surface. (Spalteholz.)



Besides possessing the individual peculiarities mentioned, the two lungs further differ from each other in general form and weight, the right lung being considerably broader and heavier than the left. The difference in length maintained by some anatomists, even if it prove constant, must be slight and of little practical importance. These differences seem to follow the asymmetry of the vault of the diaphragm and the position of the heart.

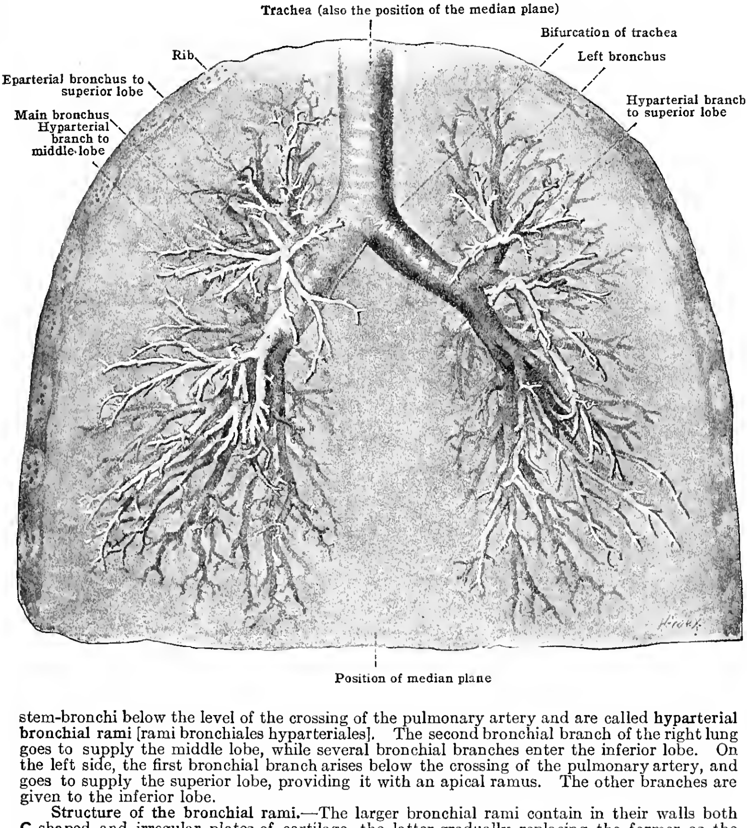
The **hilus** (fig. 994), already mentioned as situated on the mediastinal surface, presents in the left lung a raquette-shaped outline. Its average height is about 8.8 cm. (Luschka); it extends over both lobes. The hilu of the right lung, rather four-sided in outline and shorter than that of the left, is related to the three lobes. The entering structures, constituting the root of the lung (figs. 989, 993, 994), include the bronchus, pulmonary artery and veins, bronchial vessels, lymphatic vessels and glands, and pulmonary nerves. These are bound together by connective tissue and invested by the pleura. The bronchus is in the posterior and upper part of the root; the pulmonary vessels lie anteriorly, the veins below the arteries.

The surface of the lung is marked off in polygonal areas of different sizes (secondary lobules) by lines containing pigment. The pigmentation is especially deep on the lateral surface along the furrows corresponding to the ribs.

Branching of the bronchial tubes (fig. 995).—Each bronchus, from its origin at the bifurcation of the trachea, takes an oblique course to the hilus, and then continues in the lung as a main tube, extending toward the posterior part of the base. These stem-bronchi are curved, probably in adaptation to the heart, the right like the letter **C** and the left like an **S**. Throughout their course the stem-bronchi give off in monopodic fashion collateral branches, the **bronchial rami** [rami bronchiales], and these, branching in a similar way, reach all parts of the lung.

The first bronchial ramus of the right stem-bronchus arises above the place where the latter is crossed by the pulmonary artery and is named the **eparterial bronchial ramus** [ramus bronchialis eparterialis]; it supplies the superior lobe of the right lung, sending a special branch to the apex. All other bronchial rami, whether in the right or left lung, take origin from the

Fig. 995.—Cast of the Air-tubes and Their Branches, viewed from in Front. (Spalteholz.)



stem-bronchi below the level of the crossing of the pulmonary artery and are called **hyparterial bronchial rami** [rami bronchiales hyparteriales]. The second bronchial branch of the right lung goes to supply the middle lobe, while several bronchial branches enter the inferior lobe. On the left side, the first bronchial branch arises below the crossing of the pulmonary artery, and goes to supply the superior lobe, providing it with an apical ramus. The other branches are given to the inferior lobe.

Structure of the bronchial rami.—The larger bronchial rami contain in their walls both **C**-shaped and irregular plates of cartilage, the latter gradually replacing the former as the branches become smaller. The membranous wall is lost and plates of cartilage are disposed on all sides. The mucosa, with ciliated epithelium, is thrown into longitudinal folds covering bundles of elastic fibres of the membrana propria. Next to the latter is a continuous layer of smooth muscle-fibres circularly arranged. Mucous secreting **bronchial glands** [gl. bronchiales] are present as far as tubes of 1 mm. diameter; here the cartilages also disappear.

To W. S. Miller is due the credit of having greatly increased our knowledge of the finer structure of the lung and for having presented the conception of the primary lung lobule now generally accepted by anatomists. Some of the chief results of Miller's work are embodied in the following descriptions pertaining to the termination of the air-tubes and to the blood and lymph vascular systems of the lungs and pleuræ.

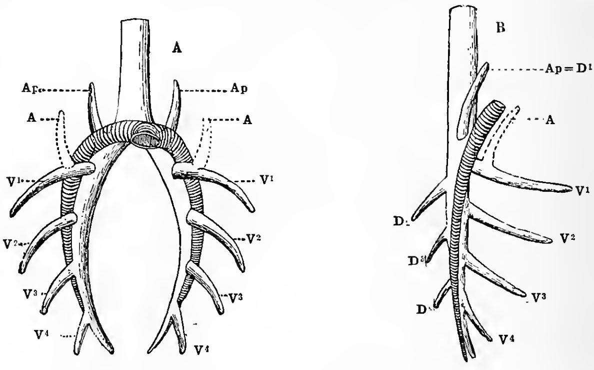
Through further branching of the bronchial rami a great number of very fine **bronchioles** [bronchioli] are reached, whose walls possess a weak muscle layer and are lined by mucosa having an epithelium of flattened non-ciliated cells. These, subdividing, give rise to the **respiratory bronchioles** [bronchioli respiratorii], the walls of which are beset with alveoli (fig. 992). From the respiratory bronchioles arise the **alveolar ducts** [ductuli alveolares], or terminal bronchi, each of which leads to a group of air-spaces, called *atria*, each of which again communicates with a second series of air-spaces, the *air-sacs* (alveolar sacs or infundibula), whose walls are pouched out to form numerous **pulmonary alveoli** [alveoli pulmonum].

A terminal bronchus with its air-spaces and blood-vessels, lymphatics and nerves, together form a **pulmonary lobule** [lobulus pulmonum], the unit of lung structure.

Aeby divided the bronchial branches into two sets, according to their relation to the pulmonary artery. The branch arising above the place where the pulmonary artery crosses the stem-bronchus he named the **eparterial bronchus**, and those arising below the crossing he called **hyparterial.** An eparterial bronchus exists only on the right side; all other branches are hyparterial. Since the eparterial supplies the superior lobe of the right lung and no eparterial branch is present on the left side, Aeby concluded that the left lung had no lobe homologous with the superior lobe of the right lung. He compared the middle lobe of the right with the superior lobe of the left lung. The collateral branches of the stem-bronchi arise in a dorsal and ventral series in the lower mammals, and the same arrangement, though less obvious, obtains in man. According to the views of Aeby and Hasse, the first ventral branch of the right side is distributed to the middle lobe, while the remaining three ventral and all the dorsal lateral branches are given to the inferior lobe. On the left side, the first ventral branch is given to the superior lobe; the other ventral branches and the dorsal branches are distributed to the inferior lobe.

Fig. 996.—Scheme of the Bronchial Tree According to Narath. A. Anterior view. B. Right lateral view. (Poirier and Charpy.)

A. Apical bronchus, collateral of the first ventral and susceptible of becoming eparterial, Ap in migrating to the bronchial trunk.



Narath considers the division of bronchial branches in accordance with their relation to the pulmonary artery as of no great morphological significance. He attributes the apparent differences on the two sides to a shifting in position of homologous branches. Thus, Narath considers that the eparterial bronchus of Aeby has become the first dorsal lateral branch by displacement above the pulmonary artery and that it is homologous with an apical branch of the left side, which retains its primitive origin from the first ventral branch (fig. 996). Narath's conception of the migration of the bronchial branches is supported by the results of Huntington's extensive studies of the bronchial tree in mammals.

The physical properties of the lungs.—The average *dimensions* in the adult male are as follows: Height of the lung is given at 25–27 cm., the greatest sagittal diameter at 16–17 cm., and the greatest transverse measurement as 10 cm. for the right and 7 cm. for the left. The *volume* of the lungs when well expanded is 6500 c.c. (Merkel.) The *weight* of the lungs can be found only approximately on account of the presence of blood and mucus. In the adult male the weight of both lungs is given as 1300 gm.; female, 1023 gm. The weight of the right lung compared with the left is as 11 is to 10. Ried and Hutchinson found the weight of the lungs compared with that of the body as 1 : 37 (male), 1 : 43 (female); in the fœtus at term, 1 : 70. After respiration has been established, the lung, if placed in water, will float. Its *specific gravity* is between 0.345 and 0.746. (Rauber.) The fœtal lung contains no air and is heavier than water. Its specific gravity is 1.045 to 1.056. (Krause.) Lung tissue, free of air, with vessels moderately filled, has likewise a specific gravity of 1.045 to 1.056. (Vierordt).

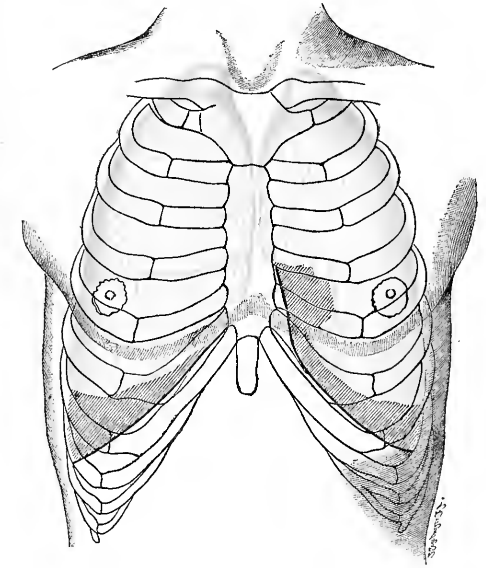
The colour of the lung results from the presence of blood, pigment, and the air in the alveoli. It varies therefore as these constituents are all or in part present and with differences in their proportions. Thus the general colour is red in the fœtus, pink, in the infant, and grey mottled with black in the adult. The dark colour is traceable to the carbonaceous matter carried into the lungs from the atmosphere.

In **consistence** the lung is soft and spongy, and when compressed between the fingers, emits a crackling sound. Among the physical properties the **elasticity** of the lung is quite remarkable: Under ordinary conditions the pressure of the air in the lung keeps the alveoli and the organ as a whole distended, but when the pleura has been opened and the air pressure equalised without and within, the lung collapses.

Topography.—The **apices** of the lungs extend upward as high as the first thoracic vertebra-a level considerably higher than the superior margin of the sternum (figs. 997, 998). The sub, clavian vein and artery and the brachial plexus, together with the anterior scalene muscle, control to a certain degree the height reached. There seems to be no constant difference between the levels attained by the apices of the two lungs. The extent to which the apex rises above the clavicle is rarely more than 3.5 cm. (Merkel), and will, of course, vary with individual differences in the position and form of this bone. The average is not over 2.5 cm. (1 in.).

The **base** of the lung, resting on the diaphragm, is separated by that thin partition from the underlying abdominal viscera: thus beneath the base of the right lung is the right lobe of the liver, while under the left lung are the left lobe of the liver, the fundus of the stomach, and the spleen. The position of the apex changes very little in respiration, and the same holds true for

Fig. 997.—Position of the Lungs from Before. (Merkel.)
The parietal pleura is shaded and outlined in black.



the hinder bulky part of the lung. The latter rests against the side of the vertebral column in the deep hollow of the angles of the ribs, and reaches below to the level of the eleventh costo-vertebral joint (fig. 998). The **anterior margins** (fig. 997) descend in curves from behind the sterno-clavicular joints, and run near together a little to the left of the median line. At the level of the sixth costo-sternal junction the anterior margin of the right lung turns lateralward to follow the sixth costal cartilage. The anterior margin of the left lung turns lateralward along the fourth costal cartilage as far as the para-sternal line, descending in a curve to the lingula and thus forming the cardiac incisure. The positions of the **inferior margins** (figs. 997, 998) of the two lungs are practically alike in their positions. Each extends in a curve convex downward, behind the sixth costal cartilage in its entire length, crosses the costo-chondral junction of the sixth rib to the superior margin of the eighth rib in the axillary line, and so to the ninth or tenth rib in the scapular line, whence they run horizontally medialward to the eleventh costo-vertebral joint.*

* These relations are the mean between the conditions observed in the cadaver and as found by physical examination of the living. In old age the inferior margins of the lungs reach a level one or two intercostal spaces lower than is the case in adult life (Mehnert).

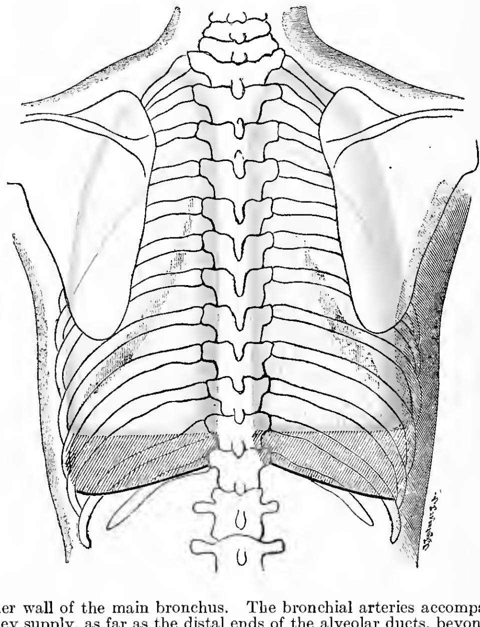
78

The **interlobar fissure** (fig. 998) begins about 6 cm. below the apex of the lung at the level of the head of the third rib. With the arm hanging at the side, a line drawn across the back from the third thoracic spine to the root of the scapular spine would indicate the course of the upper part of this fissure. (Merkel.) Thence it passes downward and around the chest to the end of the sixth bony rib in the mammillary line. Merkel points out the use of the root of the scapular spine as a landmark for finding the limits of the lobes posteriorly: with the arm hanging at the side all above this spot is superior lobe; all below it the inferior. The short fissure of the right lung begins at the main interlobar fissure in the axillary line, about the level of the fourth rib or fourth interspace, and passes nearly horizontally to the anterior margin of the lung at the level of the fourth costal arch.

The **roots** of the lungs are placed opposite the fifth, sixth, and seventh thoracic vertebræ. The right root lies behind the inferior vena cava and under the arch of the azygos vein; the left root is beneath the aortic arch and in front of the thoracic aorta. The phrenic nerve passes in front of each root, the vagus behind. On the front and back are the pulmonary plexuses, anterior and posterior. The ligament of the pleura goes from the lower edge of the root.

Vessels and nerves of the lungs.—The **bronchial arteries** (see p. 588), belonging to the systemic system, carry blood for the nourishment of the lungs. They arise from the aorta or from an intercostal artery, two for the left lung and one for the right, and, entering at the **hilus**,

FIG. 998.—POSITION OF THE LUNGS FROM BEHIND. (Merkel.)
The pleura is represented as in Fig. 997.



reach the hinder wall of the main bronchus. The bronchial arteries accompany the bronchi, whose walls they supply, as far as the distal ends of the alveolar ducts, beyond which they do not go. These vessels also supply the lymph glands of the hilus, the walls of the large pulmonary vessels, and the connective-tissue septa of the lung. **Bronchial veins** (see p. 664), anterior and posterior, arise from the walls of the first two or three divisions of the bronchi and end in the innominate and the azygos or in one of the intercostal veins; those arising from the walls of the smaller tubes, including the alveolar ducts, join the pulmonary veins. The **pulmonary artery** (see p. 528), entering the hilus in a plane anterior to the bronchus, turns to the posterior aspect of the main-stem, following its branches and their subdivisions to the lobules. Entering the lobule, the last branch of the vessel gives off as many twigs as there are atria (fig. 992), and these twigs end in dense capillary nets in the walls of the alveoli. Here the venous blood brought by the pulmonary artery, separated from the air in the alveolus only by a thin septum, is changed to arterial blood in the respiratory process. According to Miller, anastomosis between the branches of the pulmonary artery are exceptional. Anastomosis between the bronchial and pulmonary arteries has been claimed, but the connection apparently existing between these vessels is through the radicles of the bronchial veins which join the pulmonary veins. The pulmonary venous radicles begin at the capillary networks and drain the arterial blood into the pulmonary veins, which run between adjacent lobules and which receive also blood coming from the capillary network of the pulmonary pleura and from the capillary network of the bronchi (fig. 992). Thus it will be seen that while the pulmonary vein carries mainly arterial blood, it carries also some venous blood. The **pulmonary veins** (see p. 529) follow the bronchial tree on the side opposite the arteries to the hilus, where, having converged to two large trunks located in the root of the lung below the plane of the artery, they pass to the left atrium. The pulmonary veins have no valves.

Lymphatics.—Miller has found the lymphatic vessels forming a closed tube system in the walls of the bronchi, in the pleura, and along the branches of the pulmonary artery and veins. Within the lung numerous **pulmonary lymph-glands** [lymphoglandulæ pulmonales] are found chiefly at the places of branching of the larger bronchi [lymphoglandulæ bronchiales]. Scattered along the latter, as well as associated with the branches of the pulmonary artery and vein, are found masses of lymphoid tissue. Deposits of carbonaceous matter in the lymphoid structures of the lung are present, except in early infancy; the amount increases with age.

Nerves.—The vagus and sympathetic contribute to form the pulmonary plexuses in front and behind the root of the lung, from which branches go to accompany bronchial arteries; a smaller number accompany the air-tubes (see p. 957).

Variations.—Congenital absence of one or both lungs has been observed. Variations in the lobes are not uncommon—four for the right and three for the left lung has been recorded. An *infracardiac lobe,* as found in certain mammals, sometimes occurs; an infracardiac bronchus is, however, constant in man. More or less complete fusion of the middle and upper lobes of the right lung is not rare. The lungs may be symmetrical, with two lobes each, the apical bronchus of the right springing from the first ventral bronchus, as is normal for the left lung (Waldeyer, Narath); or the lungs may have three lobes each, the apical bronchus of the left arising from the main bronchus. The apical bronchus of the right lung may arise from the trachea, an origin that is normal in the hog and other artiodactyls.

Development of the lungs and trachea.—The first indication of the trachea and lungs appears in embryos of about 32 mm. as a trough-like groove in the ventral wall of the upper part of the œsophagus, communicating above with the pharynx. Later the groove becomes constricted off from the œsophagus, the constriction extending from below upward, so that a tube is formed which opens into the pharynx above. The lower end of this tube soon becomes bilobed, and the lobes, elongating, give rise to additional lobes, of which there are primarily three in the right side and two in the left. The upper unpaired portion of the tube becomes the trachea, while the lobed lower portion gives rise to the bronchi and lungs, the complicated structure of the latter being produced by oft-repeated branchings of the bronchi.

THORACIC CAVITY

Thoracic cavity [cavum thoracis] is the term used to denote the space included by the walls of the thorax and occupied by the thoracic viscera. These are, on each side, the lung, surrounded by the pleural cavity, and in the middle the pericardium and heart, great vessels, trachea and œsophagus, all closely associated and forming a dividing wall, the mediastinal septum, standing between the right and left sides of the thoracic space.

The **limits** of the thoracic space are given by the skeletal parts of the thorax together with the ligaments involved in the articulations and the muscles and membranes interposed between the bones. The arched diaphragm forms the inferior limit; and the barrier presented by the scalene muscles and the cervical fascia makes the superior boundary, which, it is to be observed, lies above the plane of the superior aperture of the thorax and therefore in the base of the neck. These boundaries are approached by the extension of the pleural cavities; yet there intervenes the parietal layer of the pleural sac which is connected with the thoracic walls by loose connective tissue, the **endothoracic fascia** [fascia endothoracica].

The **form** of the thoracic space departs from the external contour of the thorax chiefly through the projection into it of the ridge made by the succession of centra of the thoracic spine, and by the presence on either side of the latter of the broad, deep pulmonary sulcus. On account of these features a transverse section of the thoracic space is somewhat heart-shaped, but, however, much compressed antero-posteriorly (fig. 993).

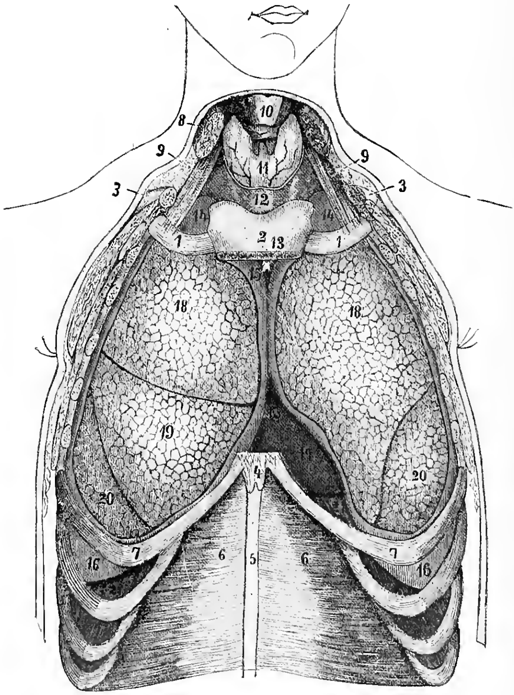
The arch of the diaphragm on the right side rises to the level of the spinous process of the seventh thoracic vertebra; on the left, to the level of the eighth thoracic spinous process. At its circumference the diaphragm is in contact to a variable extent above its origin with the inner surfaces of the costal arches. In the lower part of this zone a connection exists between the muscle and the thoracic wall through a continuation of the endothoracic fascia; in the upper part, the phrenico-costal sinus (see p. 1237) intervenes. The level reached by this deepest part of the pleural cavity is lower than the summit of the peritoneal cavity, so they overlap to a considerable extent.

THE PLEURA

The **pleura** (fig. 993) is a closed serous sac, which invests the lung (**pulmonary pleura**), and lines the inner surface of the thoracic walls (**parietal pleura**). The **pleural cavity** [cavum pleuræ] is the capillary space enclosed by the walls of the sac containing a little fluid which lubricates the apposed surfaces of the pulmonary and parietal membranes. There are two pleuræ, one in relation to each lung, completely separated by a sagittal partition, the **mediastinum.**

Fig. 999.—Pleural Cavity Opened From in Front.

1, first rib; 2, manubrium sterni; 3, acromial extremity of clavicle; 4, xiphoid process, 5, linea alba; 6, m. transversus abdominis; 7, seventh rib; 8, sternocleidomastoid m.; 9, anterior scalene m.; 10, larynx; 11, thyreoid gland; 12, deep layer of cervical fascia in front of the trachea; 13, corresponds to upper part of anterior mediastinal cave; 14, pleural cupola; 15, mediastinal pleura; 16, lower margin of costal pleura; 17, pericardium; 18, superior lobe of lung; 19, middle lobe of right lung; 20, inferior lobe of lung; 21, diaphragm. (Rauber-Kopsch.)



The **pulmonary pleura** [pleura pulmonalis] forms a smooth glistening coat over the outer surface of the lung, with the tissue of which it is inseparably connected. At the hilus the pulmonary pleura passes from the mediastinal surface of the lung to cover the root above, in front, and behind, and becomes continuous medialward with the parietal pleura of the mediastinum. Below the root of the lung the pleura is reflected medialward in a double layer as the **pulmonary ligament** [lig. pulmonale] (fig. 994).

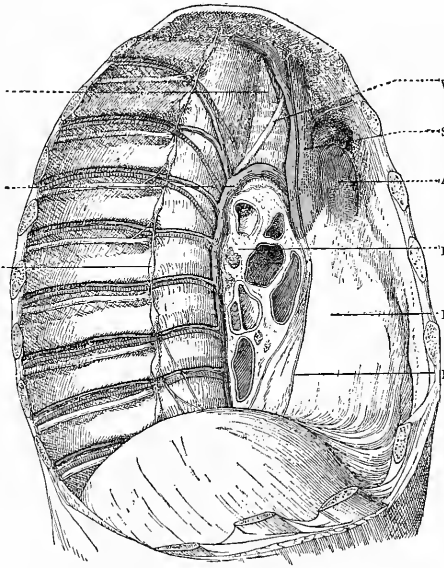
This presents anterior and posterior surfaces and three margins; the base is mostly free, and directed toward the diaphragm, with which it is connected at its medial end; the apex is at the lung root, one margin is next to the lung, and the other joins the mediastinal pleura.

The **parietal pleura** [pleura parietalis] is divided, according to the regions of the chest with which it is associated, into the costal, diaphragmatic, and mediastinal pleura. The **costal pleura** [pleura costalis] lines the thoracic wall, to which it is bound not very firmly by the endothoracic fascia. It covers incompletely the back of the sternum and extends laterally upon the ribs and intercostal muscles. Posteriorly beyond the angles of the ribs it passes over the anterior rami of the thoracic nerves and intercostal vessels, the heads of the ribs, and the sympathetic trunk to the vertebral column; here it becomes continuous with the mediastinal pleura. Above, the pleura reaches beyond the superior margin of the sternum into the root of the neck, and in the form of a dome, the **cupola** of the pleura [cupola pleuræ], is adapted to the apex of the lung. It is supported by processes of the deep cervical fascia, and by a fibrous aponeurosis known as Sibson's fascia, coming from the scalenus minimus muscle and connected with the inner margin of the first rib. In relation to the pleural cupola are those structures already described as grouped about the lung apex: the brachial plexus, subclavian artery, anterior scalene muscle, and the subclavian vein, and, on the left side, in addition, the thoracic duct.

Below, the costal pleura is continuous with the **diaphragmatic pleura** [pleura diaphragmatica], which adheres closely to the thoracic surface of the diaphragm and covers it, excepting the pericardial area and where the diaphragm and thoracic wall are in contact.

The **mediastinal pleura** [pleura mediastinalis] is reflected from before backward at the right and left sides of the mediastinum as the **laminæ mediastinales**, covering the pericardium

FIG. 1000.—RIGHT LATERAL SURFACE OF THE MEDIASTINUM AFTER REMOVAL OF THE PLEURA. (Poirier and Charpy.)



[pleura pericardiaca], to which it is closely adherent, and also the other structures of the mediastinum, with which the two layers are less firmly connected. Above the lung root the mediastinal pleura stretches directly from the spine to the sternum; but at the level of the root and below it, it is reflected laterally to the pulmonary pleura covering the root in front and behind and forming the pulmonary ligament.

The right mediastinal lamina covers (fig. 1000) the right innominate vein, the superior vena cava, the vena azygos, the trachea, the innominate artery, the right vagus and phrenic nerves, and the œsophagus. The left lamina lies against the left innominate vein, the arch of the aorta the left subclavian artery, the thoracic aorta, the left phrenic and vagus nerves, and the œsophagus. About the base of the heart-sac are a number of **adipose folds** [plicæ adiposæ) projecting from the pleura, the surfaces of which present some villous processes, the **pleural villi** [villi pleurales]; the latter also occur on the pulmonary pleura along the inferior margin of the lung.

The **lines of pleural reflexion** are of practical importance (figs. 997, 998, 1003). Posteriorly, the costal pleura simply turns forward in a gentle curve to become the mediastinal pleura, but anteriorly and inferiorly the membrane is folded upon itself, leaving intervening capillary spaces, the sinuses of the pleura [sinus pleuræ]. Such a space is present where the costal pleura is reflected upon the diaphragm, the **sinus phrenicocostalis**, the fold of the pleura occupying the upper part of the angle between the thoracic wall and diaphragm, the endothoracic fascia filling the lower part. The inferior margin of the lung enters this sinus a variable distance in inspiration. The line of the costo-diaphragmatic reflexion begins in front on the sixth costal cartilage, which it follows, descending obliquely to cross the seventh interspace in the mammillary line. The greatest depth reached is at the tenth rib or interspace in the axillary line. The line of reflexion then continues around the thorax ascending slightly to the twelfth costo-vertebral joint.

The line of reflexion behind is sometimes found as low as the level of the transverse process

Figs. 1001 and 1002.—Boundaries of the Pleuræ and Lungs.

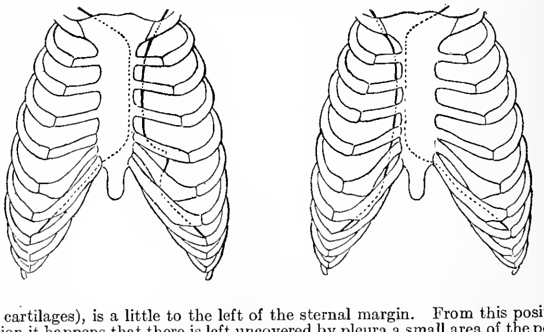
of the first lumbar vertebra. Such a possibility must be considered in operating upon the kidney.

The lines of reflexion of the costal pleura backward to the mediastinal pleura behind the sternum begin opposite the sterno-clavicular joints, descend obliquely medialward to the level of the second costal cartilage, whence they run near together or in contact, but to the left of the median line, to the level of the fourth cartilage. The reflexion on the *right* side continues from the sternum as far as the sixth rib cartilage, there turning laterally into the costo-diaphragmatic reflexion. The line on the *left* side, in the region of the cardiac notch (from the fourth

Fig. 1103.—Schematic Drawing to Represent the Maximum of Fluctuation in the Position of the Anterior Lines of Pleural Reflexion. (Tanja.)



to the sixth cartilages), is a little to the left of the sternal margin. From this position of the line of reflexion it happens that there is left uncovered by pleura a small area of the pericardium which is in contact immediately with the chest-wall. A reduplication of the pleura takes place along the anterior line of reflexion, and into the sinus costomediastinalis so formed the thin anterior margin of the lung advances in inspiration. That part of the left costo-mediastinal sinus which is in front of the pericardium is not completely filled by the margin of the lung. Although the positions of the lines of reflexion of the mediastinal pleura here described are those usually encountered, it should be noted that they are subject to variation. The extremes of variation of the anterior lines, as determined by Tanja, are indicated in fig. 1003.

Blood-vessels.—The vascular networks of the pulmonary pleura are derived from the bronchial artery and probably to some extent from the pulmonary artery which in the dog, is the only source of blood supply. The venous radicles arising from the network enter the lung. (See radicles of the pulmonary vein on page 1235.) The parietal pleura is supplied by **arteries** from several sources: internal mammary, intercostals, phrenics, mediastinal, and bronchial. The **veins** correspond to the arteries. The **lymphatics** of the pulmonary pleura form rich networks without definite relations to the lobules of the lung. They accompany the radicles of the pulmonary veins and drain into the bronchial lymph-glands. In the parietal pleura lymph-vessels are present most abundantly over the interspaces; they empty into the sternal and intercostal glands. (See p. 728.) The **nerves** supplied to the pulmonary pleura are branches from the pulmonary plexus; to the parietal pleura, from the intercostals, vagus, phrenic, and sympathetic.

MEDIASTINAL SEPTUM

The two pleural cavities are separated from each other by the **mediastinal septum** [septum mediastinale] (fig. 1000). This is a sagittal partition extending from the superior aperture of the thorax to the diaphragm between the thoracic vertebræ and the sternum, its free surfaces, right and left, formed by the mediastinal layers of the pleuræ. It is composed of the pericardium and heart and of structures which, for the most part, extend in a longitudinal direction through the thoracic cavity.

These include the œsophagus together with the vagus nerves, the thoracic duct, thoracic aorta and azygos vein; the trachea, the pulmonary vessels and the arch of the aorta with its great branches, the superior vena cava and its tributaries and the phrenic nerves; the thymus gland, internal mammary vessels and many lymph glands throughout the septum. These structures are packed together and supported by intervening connective tissue. Moreover, the connection of the sheaths of the great vessels with processes of the cervical fascia and the fixation of the pericardium to the diaphragm, give to the latter a strong support. Owing to the position of the heart, the two sides of the septum are not symmetrical, and it follows from the bulging of the left surface of the mediastinal septum that the left pleural cavity is encroached upon.

The name **mediastinal cavity** has been applied to the two regions of the mediastinal partition which find themselves located, the one in front, the other behind the plane of the heart. There is in reality no cavity, the term being used in this connection merely to donate space. Between the two spaces are interposed the pericardium and heart, the great vessels, trachea and bronchi. The **anterior mediastinal cavity** [cavum mediastinale anterius] is small. Its lateral limits are formed by the mediastinal layers of the pleuræ, right and left, which are reflected backward from the costal pleuræ of the anterior thoracic wall. The space is occupied by loose connective tissue, surrounding the thymus gland, the internal mammary vessels and a number of lymph-glands.

Recalling the lines of reflexion of the mediastinal pleuræ as above described, the form, position and extent of this space as observed from in front, will be understood; it is widest behind the inferior end of the body of the sternum and fifth and sixth costal cartilages of the left side (*area interpleurica inferior*); narrowest where the mediastinal layers are approximated behind the body of the sternum, broader again where the laminæ deviate posterior to the manubrium sterni (*area interpleurica superior*). In the latter space lies the thymus gland and the superior portions of the internal mammary vessels. In the area interpleurica inferior the pericardium comes into immediate contact with the anterior thoracic wall, and here the inferior portions of the left internal mammary vessels are found. The lymphatic vessels and glands of the anterior mediastinal space belong to the anterior mediastinal and sternal groups.

The **posterior mediastinal cavity** [cavum mediastinale posterius] (fig. 1000), limited behind by the thoracic vertebræ and laterally by the mediastinal layers of the pleuræ where they are reflected forward from the costal pleuræ of the posterior thoracic walls, is elongated and of more regular form than the anterior space. It includes the thoracic aorta, the œsophagus and vagi, the thoracic duct, azygos vein and lymph glands.

Within this space are also to be found the origins of the right intercostal arteries, the hemiazygos and, when present, the accessory hemiazygos veins, terminations of some of the left intercostal veins and the greater splanchnic nerves. The lymph glands belong to the posterior mediastinal group.

(Figs. 993, 994).—A subdivision of the mediastinal septum into anterior, middle, posterior, and superior mediastinal spaces has long been customary, and is useful for descriptive purposes.

The **superior mediastinum** is that part of the mediastinum which lies above the level of the pericardium. It extends between the first four thoracic vertebræ behind and the manubrium sterni in front, and contains the arch of the aorta and the great vessels arising from it, the innominate veins, and the upper part of the superior vena cava, the thoracic duct, the lower portion of the trachea, and a portion of the œsophagus, the phrenics, vagi, left recurrent and cardiac nerves, and the thymus gland.

From the superior mediastinum the other three divisions of the space extend downward. The **anterior mediastinum** is identical with that part of the anterior mediastinal cavity which is below the level of manubrium sterni. The **middle mediastinum** lies between the layers of the mediastinal pleuræ in front of the root of the lungs; it contains the heart, enclosed in the pericardium, and the phrenic nerves. The **posterior mediastinum** corresponds to that portion of the posterior mediastinal cavity which extends below the plane of the fifth intervertebral fibro-cartilage.

SECTION XI

UROGENITAL SYSTEM

REVISED FOR THE FIFTH EDITION

By J. PLAYFAIR McMURRICH, A.M., Ph.D., LL.D.

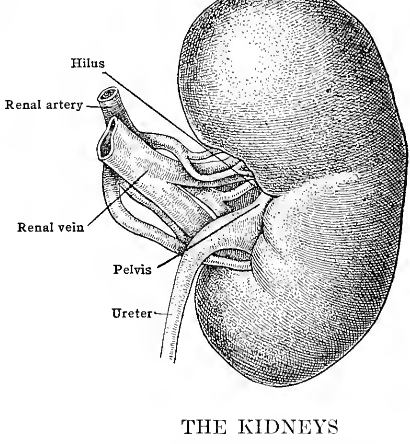
PROFESSOR OF ANATOMY IN THE UNIVERSITY OF TORONTO

The **urogenital system** [apparatus urogenitalis] includes (A) the **urinary organs** and (B) the **reproductive organs.**

A. THE URINARY ORGANS

THE organs forming the urinary apparatus [organa uropoëtica] are the **kidneys,** by which the secretion is produced; a duct, the **ureter,** proceeding from each kidney and conveying the secretion to the **bladder,** which serves as a reservoir for the urine and from which, by a single duct, the **urethra,** the secretion is carried to the exterior.

Fig. 1004.—Postero-medial Aspect of the Right Kidney.

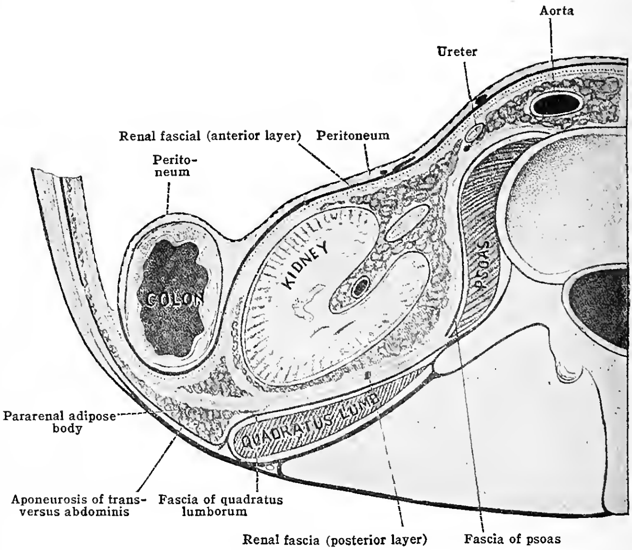


THE KIDNEYS

The **kidneys** [renes] are paired organs situated in the abdominal region and each is composed of a very great number of minute tubules, the renal tubules, enclosed within a definite and firm fibrous capsule. Each kidney is somewhat bean-shaped (fig. 1004) and is situated on the dorsal wall of the body, behind the parietal peritoneum, in such a way that the *ventral* or *visceral surface* [facies anterior] which is convex, looks obliquely ventrally and laterally, while the *dorsal* or *parietal surface* [facies posterior], usually less convex, looks dorsally and somewhat medially (fig. 1005). The *upper extremity* [extremitas superior] is usually larger than the lower [extremitas inferior] and is about 1 cm. nearer the median sagittal plane of the body, owing to the long axis of the organ being directed obliquely downward and laterally. The *lateral border* [margo lateralis] is narrow and convex, and the medial border [margo medialis], which looks medially and ventrally, is concave, its middle third presenting a slit-like aperture, the **hilus.** This opens into a cavity, called the **sinus** (fig. 1006), which is about 2.5 cm. in depth and is occupied mainly by the dilated upper extremity of the ureter, known as the renal pelvis, the interval between this and the actual kidney substance containing adipose tissue in which are imbedded the renal vessels and nerves.

Size.—The length of the kidney in the male averages 10–12 cm., its breadth about 5.5 cm. and its thickness 3 cm.; it weighs 115–150 grams. The dimensions of the female kidney are nearly as great, but its weight is from one-seventh to one-fifth less. In the child the organ is relatively large, its weight compared with that of the entire body being about 1:133 at birth; but its permanent relation, which is about 1:217, is usually attained at the end of the tenth year.

Fig. 1005.—Diagram showing Relation of Kidney to Capsule. (Gerota.)



Investment and fixation.—The surface of the kidney is covered by a thin but strong *fibrous capsule* [tunica fibrosa], which turns inward at the hilus to line the walls of the sinus (fig. 1006). It may readily be peeled off from a healthy kidney, except at the bottom of the sinus, where it is adherent to the blood-vessels entering the kidney substance and to the terminal portions of the pelvis. External to the capsule is a quantity of fat tissue, the **adipose capsule** [capsula adiposa], which forms a complete investment for the organ and is prolonged through the hilus into the sinus.

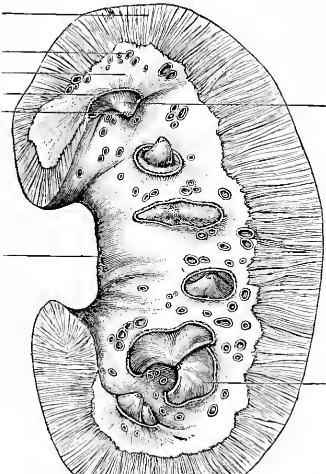
The *peritoneum,* which covers the ventral surface of the adipose capsule, has usually been regarded as the principal means of fixation of the kidney, but in reality this is accomplished by means of a special **renal fascia** (fig. 1005), developed from the subperitoneal areolar tissue (Gerota).

Renal fascia.—Lateral to the kidney there occurs between the transversalis fascia and the peritoneum a subperitoneal fascia, which, as it approaches the convex border of the kidney, divides into two layers, one of which passes in front of and the other behind the kidney, enclosing the adipose capsule. Traced medially, the anterior layer of the renal fascia passes in front of the renal vessels, and, over the aorta, becomes continuous with the corresponding layer of the opposite side; upward, it passes over the suprarenal gland and at the upper border of that organ becomes continuous with the posterior layer; and downward, it is lost in the adipose tissue intervening between the iliac fascia and muscle. The posterior layer, which is the thicker of the two, passes medially behind the renal vessels and is lost in the connective tissue in front of the vertebral column, and below it is lost, like the anterior layer, in the iliac region. Behind the posterior layer, between it and the quadratus lumborum, is a mass of adipose tissue, the **pararenal adipose body,** and both layers are united to the fibrous capsule of the kidney by trabeculæ of connective tissue which transverse the adipose capsule.

Each kidney is, accordingly, supported by these trabeculæ in a space bounded laterally and above by the layers of the renal fascia, and open medially and below. Should these trabeculæ become atrophied by wasting disease or ruptured by the pressure of the pregnant uterus, by the improper use of corsets, or by any other cause, the phenomenon of movable or wandering kidney may be set up by slight external violence, the organ tending to shift its place as far as the attachment of its vessels to the main trunks and the arrangement of the renal fascia will permit.

Position and relations.—The kidney is said to lie in the lumbar region. It is, however, intersected by the horizontal and vertical planes which separate the hypochondriac, lumbar, epigastric and umbilical regions from each other, and hence belongs to all these segments of the abdominal space. Its vertical level may be said to correspond to the last thoracic and upper two or three lumbar

FIG. 1006.—SECTION OF KIDNEY SHOWING THE SINUS. (After Henle.)



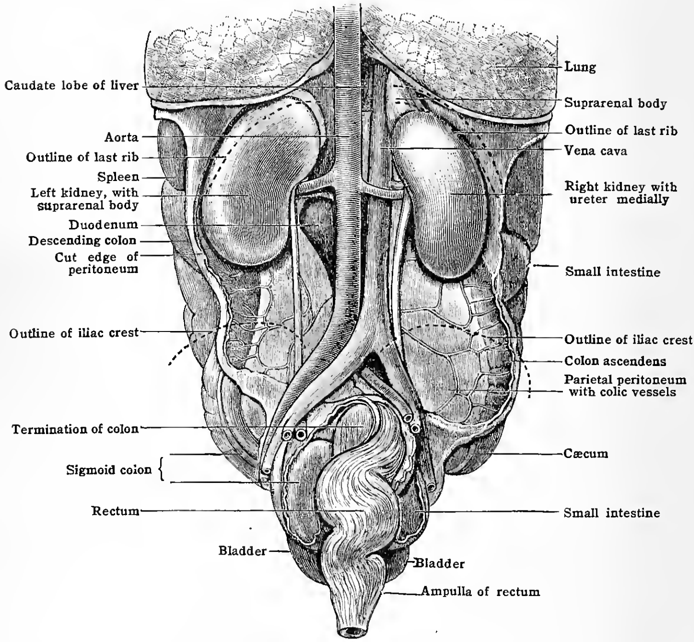
vertebræ, the right lying in most cases from 8 to 12 mm. ($\frac{1}{3}$ to $\frac{1}{2}$ in.) lower than the left; but exceptions to this rule are not infrequent.

The **posterior surface** (figs. 1007, 1008), with the corresponding portion of the fatty capsule and the pararenal adipose body, rests against the posterior abdominal wall extending upward in front of the eleventh and twelfth ribs, and medialward to overlap the tips of the transverse processes of the first and second lumbar vertebræ; the left kidney usually reaches as high as the upper border of the eleventh rib, the right only to its lower border. The only visceral relation posteriorly is on the left side, where the spleen slightly overlaps the kidney opposite the upper half of its lateral border, the adjacent surfaces of the two organs being, however, covered by peritoneum. The parietal relations (fig. 1008) on both sides are as follows: (1) the diaphragm, the left kidney, on account of its higher position, entering more extensively into this relation than the right; (2) the portion of the transversalis fascia covering the ventral surface of the quadratus lumborum; (3) the lateral border of the psoas; and (4) the last thoracic, ilio-hypogastric and ilio-inguinal nerves and the anterior divisions of the subcostal and first lumbar vessels, all of which run obliquely downward and laterally in front of the quadratus lumborum.

The **upper extremity** of each kidney is crowned by the suprarenal gland (figs. 1007, 1009), which encroaches also upon its ventral surface and medial border and is fixed to it by fibres derived from the subperitoneal tissue.

The **anterior surface** of each kidney was primarily completely covered by peritoneum that separated it from neighboring viscera, but, owing to secondary changes whereby the ascending and descending colons, the duodenum and the pancreas become retro-peritoneal organs, these come into direct relation with one or the other of the kidneys and separate portions of them from actual contact with the peritoneum. Thus, in the case of the right kidney (fig. 1009), the

Fig. 1007.—The Abdominal Viscera, seen from Behind.
(From the model of His.)
The kidneys are somewhat lower than usual in their relations to the ribs.

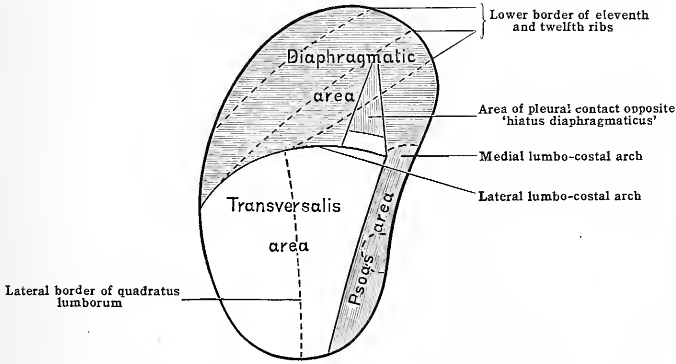


portion of the anterior surface immediately adjacent to the medial border has the descending portion of the duodenum in direct contact with it, and throughout a zone extending downward and laterally from the middle of the duodenal area to the lateral border the ascending colon and right colic flexure. Almost the entire upper half, however, and a small portion of the lower pole are covered directly by peritoneum, the upper peritoneal area having an indirect relation with the lower surface of the liver, upon which it produces the renal impression.

Similarly the anterior surface of the left kidney (fig. 1009) is in direct contact with the pancreas throughout a broad transverse band situated a little above the middle of the organ, and the splenic artery pursues its tortuous course along the upper border of this pancreatic area, while the corresponding vein is interposed between the pancreas and the surface of the kidney. The lateral portion of the lower extremity is in direct contact with the descending colon and its splenic flexure, but the remainder of the lower extremity and the whole of the upper one-fourth of the organ is directly covered by peritoneum, the upper peritoneal area having, as an indirect relation, the posterior surface of the stomach medially, and the spleen laterally (figs. 956, 1009).

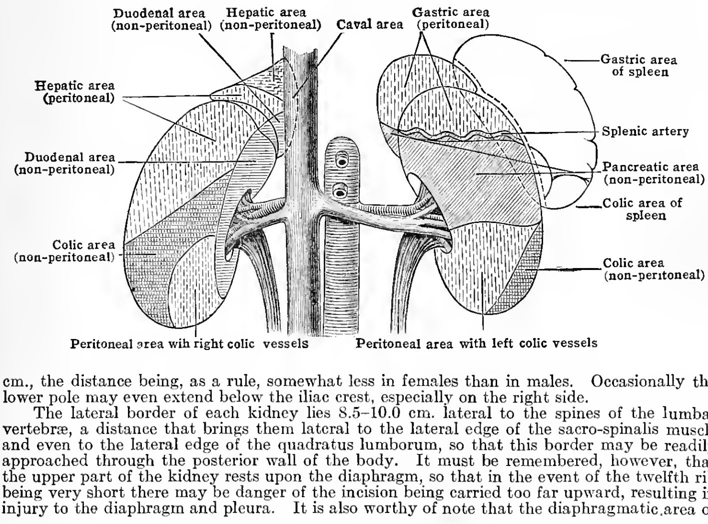
The **medial border** of the right kidney approaches the vena cava inferior very closely, especially above; that of the left is separated from the aorta by an interval of about 2.5 cm.

Fig. 1008.—Diagram of Relations of Posterior Surface of Left Kidney.



Variation in position.—The position of the kidneys in the abdominal cavity is subject to considerable variation. Thus while the upper pole of the right kidney may be said to lie typically opposite the lower half of the eleventh thoracic vertebra, it may be placed as high as the lower part of the tenth thoracic or as low as the upper half of the first lumbar. Similarly while the upper pole of the left kidney is as a rule opposite the middle of the eleventh thoracic vertebra it may lie half a vertebra higher or as low as the lower part of the second lumbar vertebra. The lower poles are distant from the crests of the ilia anywhere from 1.0 cm.–3.0

Fig. 1009.—Diagram showing Anterior Relations of Kidneys and Suprarenal Bodies.



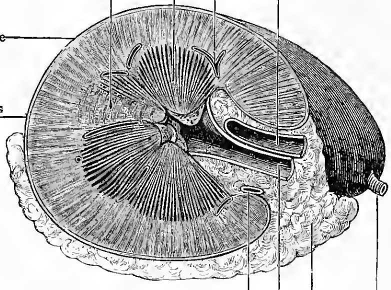
cm., the distance being, as a rule, somewhat less in females than in males. Occasionally the lower pole may even extend below the iliac crest, especially on the right side.

The lateral border of each kidney lies 8.5–10.0 cm. lateral to the spines of the lumbar vertebræ, a distance that brings them lateral to the lateral edge of the sacro-spinalis muscle and even to the lateral edge of the quadratus lumborum, so that this border may be readily approached through the posterior wall of the body. It must be remembered, however, that the upper part of the kidney rests upon the diaphragm, so that in the event of the twelfth rib being very short there may be danger of the incision being carried too far upward, resulting in injury to the diaphragm and pleura. It is also worthy of note that the diaphragmatic area of the kidney corresponds with the region where a hiatus diaphragmaticus between the costal and lumbar portions of the muscle may occur and if this be pronounced the upper part of the posterior surface of the kidney may come into more or less direct relations to the pleura (fig. 1008).

Just as there may be variation in the position of the kidneys, so too there may be considerable variation in the extent to which they are in relation to the various structures mentioned above. And this is especially true as regards their relations to the colons; for if the kidneys were lower than usual they might lie entirely beneath the line of attachment of the transverse mesocolon and thus have no direct relations with either colon, or on the other hand either the ascending or descending colon, or both, may be provided with a mesentery, whereby they would be removed from direct contact with the kidney.

Structure.—A section through the kidney shows its substance to be composed of an external or cortical [substantia corticalis] and an internal or medullary portion [substantia medullaris] (fig. 1010). The medulla consists of a variable number (eight to eighteen) of conical segments termed **renal pyramids** [pyramides renales (Malpighii)], the apices of which project into the bottom of the sinus (fig. 1006) and are received into the primary segments (calyces) of the pelvis, while their bases are turned toward the surface, but are separated from it and from each other by the cortex. The pyramids are smooth and somewhat glistening in section and are marked with delicate striæ which converge from the base to the apex and indicate the course of the renal tubules. The blunted apex, or **papilla,** of each pyramid, either singly or blended with one or even two of its fellows, is embraced by a *calyx* (fig. 1006), and, if examined with a hand-lens, will be seen to present a variable number (twelve to eighty) of minute apertures, the **foramina papillaria,** which represent the terminations of as many papillary ducts (of Bellini) through which the secretion escapes into the pelvis.

Fig. 1010.—Horizontal Section of Kidney showing the Sinus.



The **cortex** may be regarded as composed of two portions, (1) a peripheral layer, the cortex proper, which is about 12 mm. in thickness and extends from the fibrous capsule to the bases of the pyramids, and (2) processes termed **renal columns** [columnæ renales (Bertini)] which dip inward between the pyramids to reach the bottom of the sinus (fig. 1010). In section the cortex is somewhat granular in aspect, and when examined closely shows a differentiation into a number of imperfectly separated portions termed *cortical lobules* [lobuli corticales]. Each of these is composed of a *convoluted portion* [pars convoluta], surrounding an axial *radiate portion* (pyramid of Ferrein) [pars radiata (processus Ferreini)]. The latter consists of a group of tubules which extend from the cortex into the base of one of the medullary pyramids, whence it is also termed a medullary ray; and each medullary pyramid is formed from the rays of a number of cortical lobules, these structures, therefore, greatly exceeding the pyramids in number.

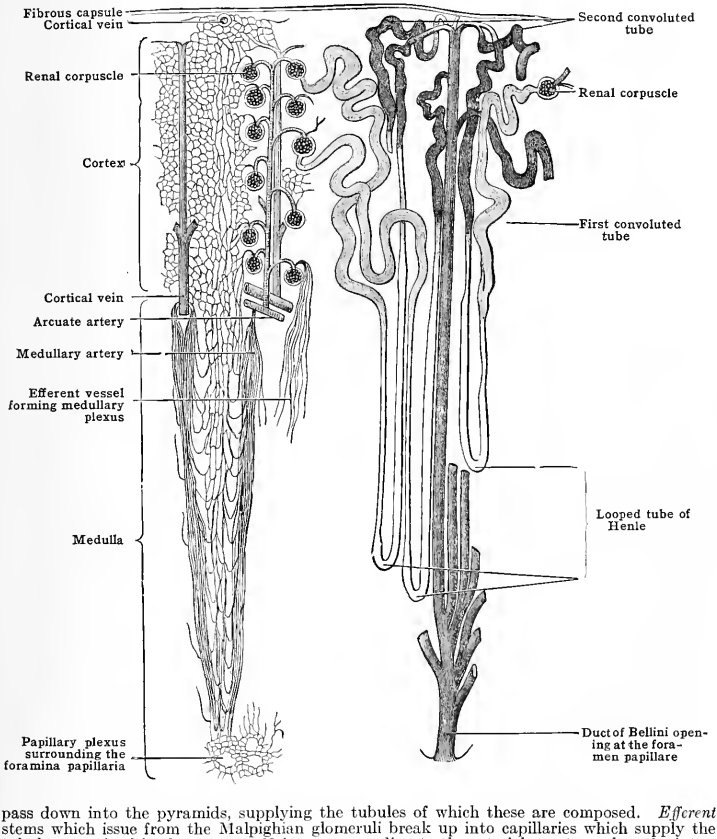
Renal tubules (fig. 1011).—The structure described above is the result of the arrangement of the renal tubules, which constitute the essential units of the kidney. Each of these commences in a spherical **glomerular capsule** (fig. 1011), one wall of which is invaginated by a small *glomerulus* of blood-vessels, the combination of glomerulus and capsule forming what is termed a **renal (Malpighian) corpuscle.** These corpuscles are situated in the convoluted portions of the cortical lobules, and from each of them there arises by a narrow neck a tubule, which quickly becomes wide and convoluted, this portion being termed the **first convoluted tubule.** This enters a medullary ray, where it narrows again and descends as a straight tubule, the **descending limb of Henle's loop,** into the subjacent medullary pyramid, and, turning upon itself, forming the **loop of Henle,** ascends to the cortex, where it again becomes wide and contorted, forming the **second convoluted tubule.** This again lies in the convoluted portion of the cortical lobule, and, becoming narrower, opens with other similar tubules into a straight or **collecting**

tubule, which occupies the axis of the medullary ray. Then, descending into the subjacent medullary pyramid, it unites with other collecting tubules, and finally opens into the renal pelvis at the summit of a papilla.

The tubules are lined with epithelium throughout, the cells being tesselated in the capsule, irregularly cubical in the convoluted tubules and ascending limbs, flattened on the descending limbs and loops of Henle, and columnar in the cortical collecting tubules and in the straight tubules of the medulla.

Vessels (fig. 1011).—The kidney is very vascular. The larger *arterial branches,* arranged in the sinus as has already been described, enter the substance of the kidney and pass up as the *interlobar arteries* in the renal columns. On reaching the bases of the pyramids they bend so as to run horizontally between these and the cortex, forming the *arcuate arteries* [arteriæ arciformes] from which interlobular branches pass up into the cortex and supply *afferent* branches to the Malpighian glomeruli. From the arcuate arteries numerous branches, the *arteriolæ rectæs,*

Fig. 1011.—Scheme of Tubules and Vessels of the Kidney.



pass down into the pyramids, supplying the tubules of which these are composed. *Efferent* stems which issue from the Malpighian glomeruli break up into capillaries which supply the tubules contained in the cortex. *Veins* corresponding to the arteriolæ rectæ and to the interlobular, arcuate and interlobar arteries occur, opening into the renal veins, and, at the surface of the kidney, arranged in star-like groups, are the *stellate veins* [venæ stellatæ], which open into the interlobular veins and also communicate with the veins of the adipose capsule. The renal *lymphatics* may be divided into two sets, capsular and parenchymatous. They terminate in the upper lumbar nodes.

Nerves.—The nerves form a plexus accompanying the vessels, and are derived from the sympathetic and vagus through the renal plexuses.

Variations.—The kidney of a fœtus differs from that of the adult in being divided into a number of distinct renal lobes, each of which corresponds to the base of a renal pyramid and is capped by a thin layer of cortex. Such a condition is permanent in some of the lower animals; but in man the superficial indications of morphological segmentation usually become obliterated during the progress of growth of the cortical tissue, and are seldom visible after the age of ten.

Development.—In the development of the embryo, representatives of three different sets of excretory organs occur, the permanent kidney (metanephros) being the last to form. The two earlier sets (pronephros and mesonephros) have a common duct, the **Wolffian duct,** and from the lower end of this an outgrowth develops, which extends upward on the posterior abdominal wall and comes into connection with a mass of embryonic tissue known as the **metanephric blastema.** The outgrowth gives rise to the ureter, pelvis and collecting tubules, while the remaining portions of the tubules are formed from the blastema.

Various *abnormalities* may result from modifications of the development of the kidneys. (1) Occasionally the ureteric outgrowth of one side fails to develop, the result being the occurrence of a single kidney. (2) The blastema may fail to attain its normal position, in which case the kidney may be situated in the iliac region or even in the pelvis; or the blastema may be drawn into an unusual position, the kidney resting on the vertebral column, or even on the opposite side of the abdomen; (3) or the two blastemas may fuse to a greater or less extent, forming a "horse-shoe kidney," extending across the vertebral column; or, if the fusion be more extensive, an apparently single kidney, which may rest upon the vertebral column, or to one side of it. Such fused kidneys may be distinguished from single kidneys by the fact that they possess two ureters opening normally into the bladder. (4) In rare cases, a blastema may become divided, an accessory kidney of varying size being thus produced. (5) Finally, in one or more of the tubules there may be a failure of the union of the portion derived from the blastema with the collecting tubule derived from the ureteric upgrowth, and the secretion having no means of escape from such malformed tubules, they become greatly dilated, producing a cystic kidney.

THE URETERS

The **ureter** (figs. 1004, 1007, 1012, 1015), which serves as the excretory duct of the kidney, is a canal, expanded and irregularly branched above, but narrow and of fairly uniform dimensions throughout the rest of its course. At its origin in the renal sinus it consists of a number of short tubes, usually eight or nine, called **calyces minores** (fig. 1012), each of which embraces a renal papilla, or occasionally two papillæ may be connected with a single calyx. These calyces minores open directly or by means of short intermediate tubes (**infundibula**) into two short passages, the superior and inferior **calyces majores,** which in turn unite after a longer or shorter course to form the **pelvis.** Occasionally a third or middle calyx major is present.

The **pelvis** [pelvis renalis] (fig. 1012) is usually more or less funnel-shaped, being wider above, where it lies between the two lips of the hilus, and narrower below, where it arches downward and medially to become continuous with the ureter proper. It is, however, very variable in shape and in some cases is hardly larger than the ureter. Usually it is flattened dorso-ventrally so that its anterior and posterior walls are in contact and its cavity represented merely by a fissure. The majority of the branches of the renal vein and artery lie in front of it, imbedded in fat tissue, and anterior to these are the descending portion of the duodenum on the right side and the pancreas on the left. The intra-renal portions of the ducts, including the pelvis, are considered parts of the kidney.

The **ureter** proper (fig. 1007) extends from the termination of the pelvis to the bladder, its course lying in the subperitoneal tissue. It is a tube about 5 mm. in diameter when distended and it is fairly uniform in size, except that a slight constriction occurs where it enters the pelvis and a second one occurs at about the middle of its abdominal portion. Its length is variously stated, but the average in the male adult may be taken as about 30 cm., the right being usually a little the shorter.

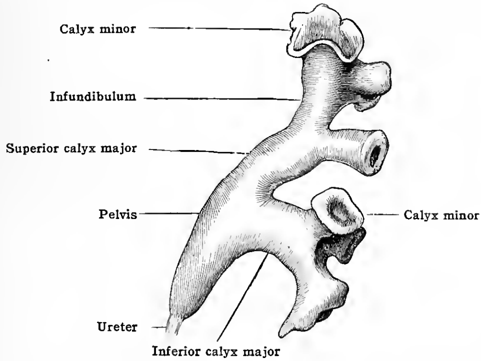
Course and relations.—The course of each ureter may be conveniently divided into three portions, abdominal, pelvic, and vesical. The **abdominal portion** [pars abdominalis] runs downward and slightly medially and is in relation *posteriorly* with the psoas muscle and its fascia; it crosses the genito-femoral nerve obliquely and in the lower part of its course passes in front of the common iliac artery near its bifurcation. *Anteriorly* it is covered by peritoneum and is crossed by the spermatic or ovarian vessels. *Medially* it is in relation on the right side with the inferior vena cava and on the left with the aorta, the vein being almost in contact with the right ureter, while the artery is separated from the left one by an interval that diminishes from 2.5 cm. above, to 1.5 cm. opposite the bifurcation of the vessel.

The **pelvic portion** [pars pelvina] passes in front of the sacro-iliac articulation and then forward and downward upon the obturator internus and its fascia behind and below the psoas, crossing the obturator vessels and nerve and having anterior to it in the female the posterior border of the ovary. It thus reaches the level of the floor of the peritoneal cavity, whereupon, at about the level of the ischial spine, its course is directed forward and medially toward the bladder. In this part of its course *in the male*, it is crossed superiorly and medially by the ductus deferens, and then passes under cover of the free extremity of the vesicula seminalis, separated from its fellow by a distance of 37 mm. *In the female* it runs parallel with, and 8 to 12 mm. distant from, the cervix uteri, passes behind the uterine artery, through the uterine plexus of veins, and beneath the root of the broad ligament, and finally crosses the upper third of the lateral wall of the vagina to reach the vesico-vaginal interspace and enter the substance of the bladder at about the junction of its posterior, superior and lateral surfaces.

The **vesical portion,** about 12 mm. in length, runs obliquely downward and medialward through the coats of the bladder, and opens on its mucous surface about 20 to 25 mm. from both its fellow and the internal urethral orifice.

Structure.—The wall of the ureter is about 1 mm. ($\frac{1}{25}$ in.) in thickness, and consists of a mucous membrane, a muscular coat, and an external connective-tissue investment. The mucous membrane is longitudinally plicated, and is lined by transitional epithelium, continuous with that of the papillæ above and with that of the bladder below. Mucous follicles of simple form have been found in the upper part of the canal. The muscularis is about 0.5 mm. (1/50 in.) in thickness, and consists of two layers, an external, composed of annular fibres, and an internal,

FIG. 1012.—PELVIS AND UPPER PORTION OF URETER. (After Henle.)



of fibres longitudinally disposed. After the tube has entered the bladder the circular fibres form a kind of sphincter around its vesical orifice; while the longitudinal fibres are continued onward through the wall of the bladder and terminate beneath its mucous membrane.

Vessels and nerves.—The *arteries* supplying the pelvis and upper part of the ureter come from the renal; the rest of the abdominal portion of the ureter is supplied by the spermatic (or ovarian), and its pelvic portion receives branches from the middle hæmorrhoidal and inferior vesical; the *veins* terminate in the corresponding trunks; and the *lymphatics* pass to the lumbar and hypogastric nodes. The *nerves* are supplied by the spermatic, renal, and hypogastric plexuses.

Variations.—Occasionally the depression which separates the two calyces majores extends through the pelvis, so that the calyces appear to open directly into the ureter. The fission may also affect the ureter to a greater or less extent, in extreme cases producing a duplication of the tube throughout its entire length.

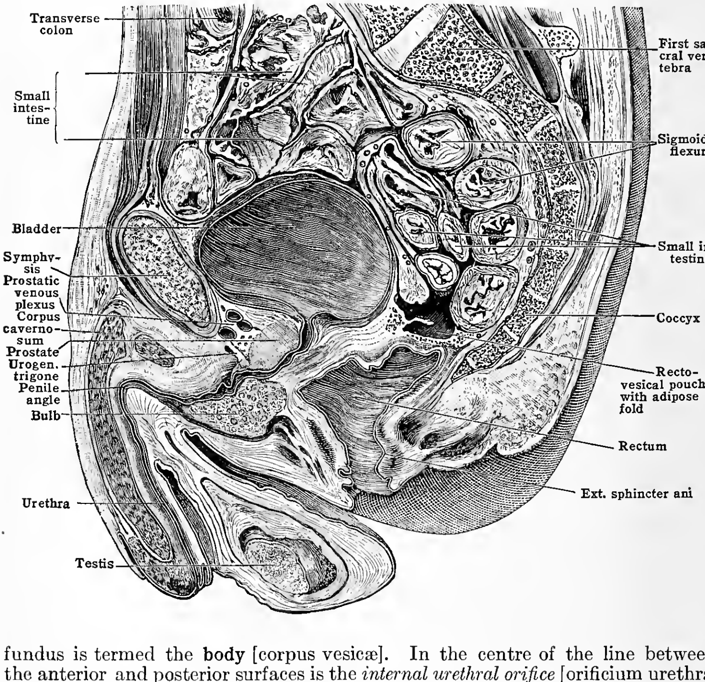
THE URINARY BLADDER

The **urinary bladder** [vesica urinaria] is a receptacle, whose form, size, and position vary with the amount of its contents. The adult organ in its empty or moderately filled condition lies entirely below the level of the oblique plane of the pelvic inlet; but when considerably distended it rises into the abdomen and shows itself beneath the parietes as a characteristic mesial projection above the symphysis, a projection which in extreme distention of the bladder may extend nearly to the level of the umbilicus.

Form.—When distended it assumes in the male an ovoid shape with its longest diameter directed from above downward and backward; but in the female the transverse diameter is the greatest, in accordance with the greater breadth of the pelvic cavity. In the child it is somewhat pear-shaped, the stalk being represented by the urachus.

Parts.—For convenience in description five surfaces may be recognized, but they are but indistinctly separated from each other. One, the **anterior or pubic surface,** is directed forward and downward; second, the **superior or intestinal surface,** looks upward; the third, the **posterior surface,** looks backward; and the other two are the **lateral surfaces.** The anterior, superior, and lateral surfaces meet at the **vertex** of the bladder, from which the **middle umbilical ligament (urachus)** extends to the umbilicus; the posterior surface, sometimes flat and sometimes, especially in old age, convex, forms what is known as the base or **fundus** [fundus vesicæ]; and the portion of the viscus intervening between the vertex and

Fig. 1013.—Median Sagittal Section of the Male Pelvis.
(From a preparation in the Museum of St. Thomas's Hospital.)



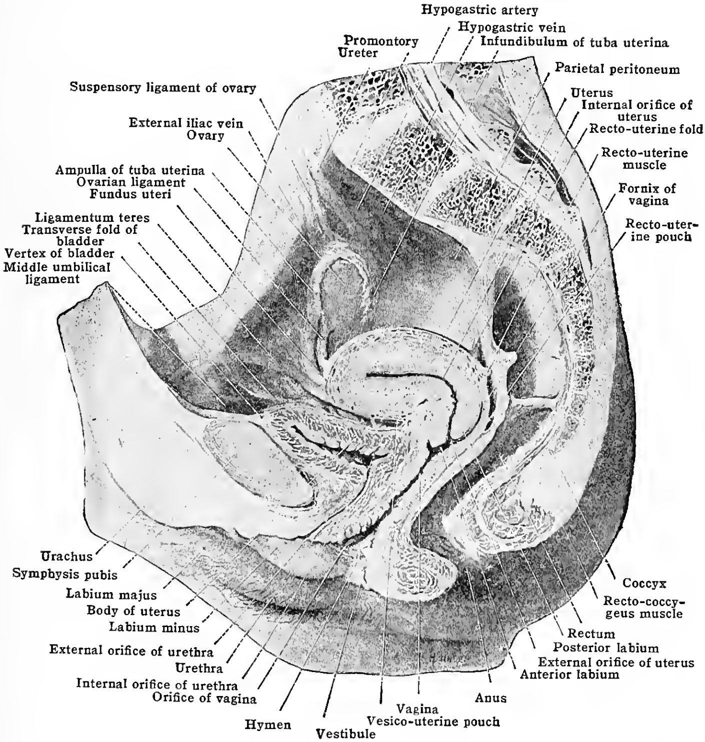
fundus is termed the **body** [corpus vesicæ]. In the centre of the line between the anterior and posterior surfaces is the *internal urethral orifice* [orificium urethræ internum], by which the bladder communicates with the urethra, and the portion of the organ immediately surrounding this is sometimes spoken of as the **neck.**

When the bladder is empty and relaxed, the superior surface sinks down upon the anterior and posterior surfaces, thus becoming concave, and the cavity of the organ is reduced to a **T-** or **Y**-shaped fissure. In the female, the cavity of the empty bladder in mid-sagittal section often more nearly resembles a figure **7** (see fig. 1014).

Relations.—The anterior surface looks downward and forward toward the symphysis pubis (figs. 1013, 1014). It is uncovered by peritoneum, but is separated from the pubic bones and anterior attachments of the obturatores interni and the levatores ani by a space known as the **prevesical space (cavum Retzii),**

which contains a variable quantity of loose fat continuous with the pelvic and abdominal subperitoneal tissue. Each lateral surface is covered by peritoneum down to the level at which it is crossed obliquely from behind forward and upward by the obliterated hypogastric artery. Below this level it is separated from the levator ani and obturator internus by subperitoneal tissue, which usually bears much fat in its meshes and ensheaths the vesical vessels and nerves. It is also crossed by the ductus deferens, which passes between the ureter and the wall of the bladder, a little above the level at which the former enters the wall of the bladder, at the junction of its lateral and posterior surfaces and about 3.5 cm. above the fundus. The posterior surface may be divided into two portions, an upper covered by the peritoneum of the recto-vesical or vesico-uterine pouch (fig. 1013), and a lower in direct contact *in the male* with the anterior wall of the

Fig. 1014.—Mid-sagittal Section of the Female Pelvis. (Spalteholz.)



rectum and with the lower part of the ductus deferentes and the vesiculæ seminales. Between the diverging ductus deferentes there is a triangular space, whose base is formed by the line of reflexion of the recto-vesical pouch of peritoneum and the apex by the meeting of the ejaculatory ducts at the summit of the prostate. It represents the area of direct contact of the posterior wall of the bladder with the rectum. *In the female* the posterior surface is adherent in its lower part to the cervix of the uterus and the upper part of the anterior wall of the vagina (fig. 1014), but it is separated above from the body of the uterus by the shallow vesico-uterine pouch of peritoneum.

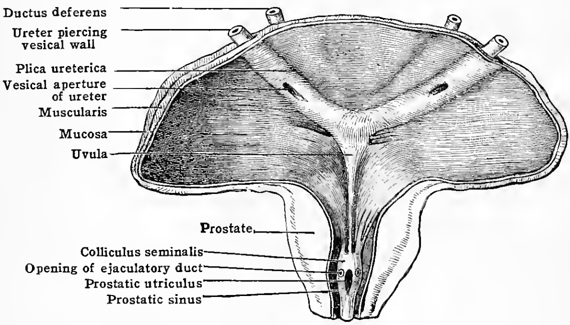
The superior surface is entirely covered by peritoneum. It looks almost directly upward into the abdominal cavity and has resting upon it coils of the small intestines and sometimes a portion of the sigmoid colon behind these.

Variation in position.—In the normal condition the bladder of the adult lies below the upper border of the symphysis pubis, but if fully distended it may rise above this level, carrying with it the reflexion of peritoneum from its upper surface to the anterior abdominal wall. The anterior surface of the bladder is thus brought into relation with the anterior abdominal wall, being separated from it only by the enlarged prevesical space, and it is thus possible to enter the bladder above the symphysis pubis without penetrating the peritoneum.

In the infant, owing to the smaller extent of the pelvic cavity, the bladder lies at a somewhat higher level than in the adult and rises into the abdominal cavity. Indeed the entire bladder is above the horizontal level of the pubic crests, the urethral orifice being behind the upper margin of the symphysis pubis. As the child learns to walk, however, this position gradually alters and usually by the age of six years the adult relations have been acquired.

The fixation of the bladder.—The reflections of the peritoneum from the superior surface of the bladder to the anterior abdominal wall and from the sides and back to the corresponding walls of the pelvis are sometimes described as the superior, lateral and posterior *false ligaments.* Furthermore there extends from the apex of the bladder to the umbilicus a fibrous cord, the *urachus,* the remains of the embryonic allantois; this is described as the *middle umbilical ligament* of the bladder (fig. 1014), and *lateral umbilical ligaments* are formed by the obliterated hypogastric arteries which carried the fœtal blood to the placenta and in the

Fig. 1015.—The Posterior Wall of the Bladder. (After Henle.)



adult are represented by fibrous cords passing over the sides of the bladder and ascending to the umbilicus.

In addition to these structures certain thickenings of the endopelvic fascia, where it comes into relation with the base of the bladder and prostate gland, constitute what are termed the **true ligaments.** Two such thickenings extend from the anterior surface of the capsule of the prostate gland, or from the lower part of the anterior surface of the bladder in the female, to the pubic bones and constitute what are known as the *middle pubo-prostatic* (*pubo-vesical*) *ligaments,* with which muscle fibres [m. pubovesicalis] are usually associated. Similarly, thickenings of the fascia extending from the sides of the prostate gland or from the sides of the base of the bladder to the lateral walls of the pelvis form the *lateral true ligaments.*

Muscle fibres [m. rectovesicalis] also occur in the subperitoneal tissue contained within the peritoneal folds (posterior false ligaments) extending from the back of the bladder to the posterior wall of the pelvis and bounding the recto-vesical pouch of peritoneum in the male. They correspond to the *mm. rectouterini* of the female.

The internal surface.—The mucous membrane lining the internal surface of the bladder is soft and rose-coloured during life, and in the empty bladder is thrown into irregular folds which become effaced by distention. It is modified over a triangular area at the base of the bladder, termed the *trigone* [trigonum vesicæ (Lieutaudi)] (fig. 1015) whose three angles correspond with the orifices of the urethra and of the two ureters, and are separated from one another by a distance of 20 to 25 mm. This area is paler in colour and free from the plication that characterizes the rest of the mucous membrane; it is bounded posteriorly by a transverse ridge, the *plica ureterica,* extending between the orifices of the ureters, and toward the urethral orifice presents a median longitudinal elevation, the *uvula vesicæ,* which is apt to be especially prominent in aged persons. The *internal urethral orifice* is normally situated at the lowest point of the bladder, at the junction of the anterior and posterior surfaces. It is surrounded by a more or less distinct circular elevation, the *urethral annulus,* and is usually on a level with about the center of the symphysis pubis and from 2.0 to 2.5 cm. behind it.

Structure.—The general characteristics of the *mucous membrane* of the bladder, which is lined by epithelium of the transitional variety, have already been described. It rests upon a loose *submucous tissue,* which contains numerous elastic fibres. The greater part of the thickness of the wall is formed, however, of the *muscular coat,* consisting of non-striped muscle tissue, the fibres of which are arranged in three more or less distinct layers. The *outer layer* is composed mainly of longitudinal fibres, some of which are continued forward to the pubis from the neck of the bladder to form the mm. pubovesicales and others backward to form the mm. rectovesicales. To this outer layer the term *m. detrusor urinæ* has been applied, but it should be noted that it does not contract independently of the circular layer. The *middle ayer* is thicker than the outer and more uniformly developed. It consists of fibres having for the most part a circular direction and is well developed over all the upper portion of the bladder, but becomes thinner in the region corresponding to the trigone. It is here that the *inner layer* is chiefly developed, consisting of fibres, which are situated partly in the submucous tissue and have a general longitudinal direction throughout the region of the trigone. At the neck of the bladder, however, they form a strong circular bundle, which is continued into the prostatic portion of the urethra and forms what is termed the *internal sphincter* of the bladder.

Vessels.—The *arteries* of the bladder are usually two in number, the superior and inferior vesical, branches of the hypogastric artery; the fundus also receives branches from the middle hæmorrhoidal and in the female twigs are also sent to it from the uterine and vaginal arteries. The *veins* form an extensive plexus at the sides of the bladder, from which stems pass to the hypogastric trunk. The *lymphatics* accompany the veins and communicate with the hypogastric nodes, some of those from the fundus passing to nodes situated at the promontory of the sacrum.

Nerves.—The *nerves* are derived partly from the hypogastric sympathetic plexus and partly from the second and third sacral nerves. The fibres from the latter constitute the nervi erigentes, stimulation of which produces contraction of the general musculature and relaxation of the internal sphincter. On each side of the bladder there is formed a sympathetic *vesical plexus,* from which *superior* and *inferior vesical* nerves pass to the corresponding parts of the bladder.

Development.—In the earlier stages of development the urogenital ducts and the digestive tract open below into a common cavity, the *cloaca,* from the ventral portion of which a long tubular outgrowth, the *allantois,* extends out to the placenta through the umbilical cord. Later the cloaca becomes divided in the frontal plane into a ventral portion which receives the urogenital ducts, and a dorsal portion, which becomes the lower end of the rectum. From the upper part of the ventral portion the bladder is developed. Since the cloaca is lined by endoderm the mucous membrane of the bladder is mainly derived from that embryonic layer, but it is worthy of note that portions of the lower ends of the ureters are taken up into the wall of the bladder, giving rise to the area of the trigone, whose mucous membrane is thus of mesodermal origin. The portion of the allantois within the body of the fœtus is transformed after birth into a fibrous cord, the *urachus.*

The **urethra** will be considered later in connection with the reproductive organs.

B. THE REPRODUCTIVE ORGANS

The reproductive organs include those of the male [organa genitalia virilia] and those of the female [organa genitalia muliebria].

THE MALE REPRODUCTIVE ORGANS

The reproductive organs of the male consist of (1) two **testes** in which the spermatozoa are formed, (2) their ducts, the **ductus deferentes**; enclosed throughout a portion of their course in the **spermatic cord**; and the **seminal vesicles,** reservoirs for the semen, connected with the ductus deferentes; (3) the **penis,** the organ of copulation, which is traversed by the urethra; (4) the **urethra,** a canal into which the ductus deferentes open and which also gives exit to the contents of the bladder; (5) the **prostate gland,** a musculoglandular structure surrounding the beginning of the urethra; (6) the **bulbo-urethral glands** which open into the urethra.

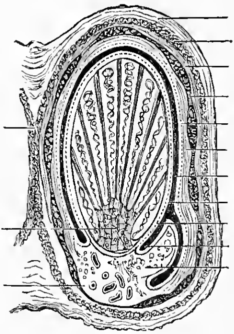
1. The Testes and Their Appendages

The scrotum.—The two testes, together with the beginning of the ductus deferentes, are contained within a pouch, the *scrotum,* which is divided into two compartments by a median sagittal septum, the edge of which is indicated on the surface by a ridge-like thickening of the integument, termed the *raphe.*

This double condition of the scrotum is explained by its origin from the fusion of two outpouchings of the lower portion of the abdominal wall, the inguinal canals forming, as it were, the necks of the outpouchings. The testes are primarily retroperitoneal abdominal organs, but later they descend through the inguinal canals into the scrotal outpouchings, where they lie between the peritoneal sac which each of these contains and the remaining layers of the wall, thus retaining their retroperitoneal position. The peritoneal sacs are at first in communication with the abdominal cavity, but after the descent of the testes each undergoes degeneration in its upper part, the cavity disappearing and the peritoneal tissue becoming converted into a portion of the connective tissue in which the ductus deferens and the vessels and nerves associated with it are imbedded in their course through the *spermatic cord.* The portion of the sac in relation with each testis persists, however, and wrapping itself around that structure forms for it a serous investment, the *tunica vaginalis propria* (fig. 1016).

The *integument* of the scrotum is more or less pigmented and presents numerous transverse ridges extending laterally on either side from the raphe. It is furnished in the adult with coarse, scattered hairs and its sebaceous and sudoriparous glands are well developed. The deeper layers of the dermis, have a pinkish colour, and form what is termed the *dartos* (fig. 1016), the colouration being due to the

Fig. 1016.—Horizontal Section of the Scrotum and Testis. (Diagrammatic.)

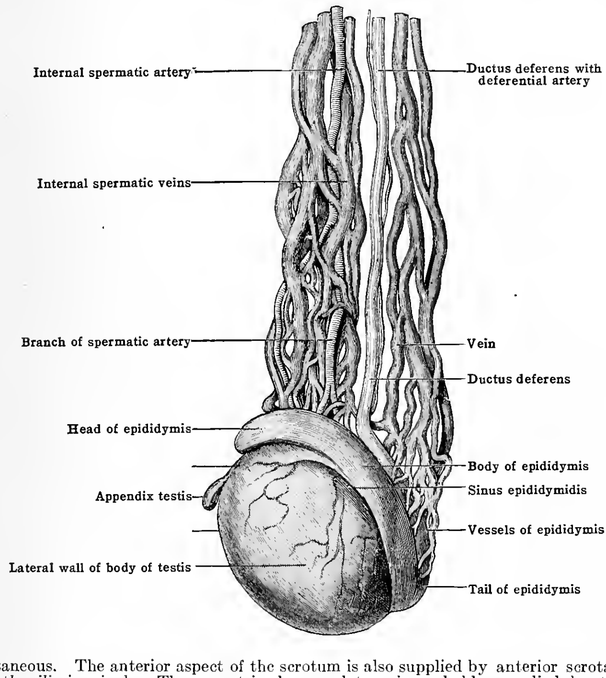


presence in it of numerous non-striated muscle fibres, which are for the most part arranged at right angles to the wrinkles of the surface and are the cause of these. The more superficial fibres of the dartos, like the rest of the integument, form a common investment for both testes, but the deeper ones of either side bend inward at the raphe and assist in the formation of the septum.

Internal to the dartos and closely related to it is a layer of laminated connective tissue, the *cremasteric fascia.* It is destitute of fat and is continuous at the subcutaneous inguinal ring with the intercrural fibres, being probably the scrotal representative of the external oblique muscle. It is succeeded by a strong sheet of fascia containing longitudinal bands of striated muscle tissue, forming what is termed the *cremaster muscle* (figs. 389, 1016) and being continuous above with the fibres of the internal oblique muscle of the abdomen. Internal to this is a thin layer of connective tissue, the *tunica vaginalis communis,* which is continuous with the transversalis fascia at the inguinal ring, and, finally, there is the *tunica vaginalis propria,* which forms the serous investment of the testis and, as has been stated, is of peritoneal origin. Like other similar serous investments it has the form of a double sac, the outer or parietal layer of which is closely adherent to the tunica vaginalis communis and contains numerous nonstriped muscle fibres forming what has been termed the *internal cremaster muscle.* The inner or visceral layer is thinner and closely invests the testis and a portion of the epididymis, being reflected from the inferior and posterior parts of the latter to be continuous with the parietal layer. Toward the upper part of the lateral surface of the testis it is folded in between that structure and the epididymis, forming a well-marked pocket, the *sinus epididymidis* (digital fossa) (fig. 1017), whose upper and lower lips form what are termed the *ligamenta epididymidis.*

Vessels and nerves.—The skin and dartos of the scrotum are supplied partly by the perineal branch of the internal pudendal *artery* and partly by the external pudendal branches of the femoral. The deeper layers are supplied by the spermatic branch of the inferior epigastric. The *veins* accompany the arteries, the external pudendals opening into the internal saphenous vein near its termination. The *lymphatics* terminate in the more medial inguinal nodes. Several *nerves* take part in the supply of the scrotum. The external spermatic branch of the genito-femoral gives sensory branches to the anterior and lateral surfaces and also supplies the external cremaster muscle; the posterior surface is supplied by the perineal branch of the pudendal nerve; and the inferior surface by the perineal branches of the posterior femoral

Fig. 1017.—The Left Testis with Vessels and Duct. (After Sappey.)



cutaneous. The anterior aspect of the scrotum is also supplied by anterior scrotal branches of the ilio-inguinal. The non-striped musculature is probably supplied by the internal spermatic nerve from the hypogastric plexus.

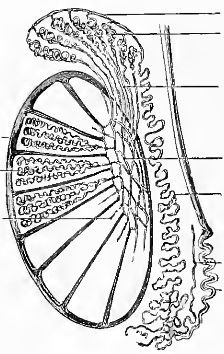
Hernia.—The communication of the tunica vaginalis propria with the abdominal peritoneum is usually obliterated within a few days after birth, but sometimes the process of obliteration is more or less incomplete. If the communication remains open there is a free passage for a loop of the intestine to enter the cavity of the tunica vaginalis, such a condition constituting what is known as the *congenitol* variety of inguinal hernia. If the communication be interrupted only at the upper part of the original sac, so that the cavity of the tunica vaginalis propria extends a considerable distance up the spermatic cord a hernia, passing through the inguinal canal, may invaginate the upper part of the tunica vaginalis into the lower, producing what is termed the *encysted* variety of hernia. Or if, finally, the obliteration of the communication begins in the neighbourhood of the testis, a funnel-shaped prolongation of the peritoneal cavity may extend downward into the spermatic cord, and hernia into this constitutes the variety known as *hernia into the funicular process.*

The testis and epididymis.—The testes (fig. 1017) are the essential male organs of reproduction and are contained within the scrotum. They are two in number, each being of a flattened oval form, with two *surfaces*, *medial* and *lateral*, two *borders*, *anterior* and *posterior*, and two *extremities*, *superior* and *inferior*. To the whole of the posterior border there is attached the *epididymis*, formed by the efferent ducts. The testis is obliquely placed, so that the medial surface also looks somewhat forward and downward.

The surface of the testis is covered by the visceral layer of the tunica vaginalis propria except where it is in contact with the epididymis, and is formed by a dense white inelastic capsule, the *tunica albuginea*, beneath which is a looser and more vascular layer known as the *tunica vasculosa*. From the inner surface of the albuginea, lamellæ of connective tissue, known as *septula*, converge toward the posterior border of the testis and toward its upper part unite together to form a network (fig. 1018), the *mediastinum testis* (or corpus Highmori), through which blood-vessels and lymphatics enter and leave the testis, while by the interspaces of the network, known as the *rete testis*, the tubules of the testis are placed in communication with the epididymis.

The septula divide the substance of the testis into a number of compartments or *lobules*, each of which is occupied by a number of slender, greatly contorted canals, the *seminiferous tubules* [tubuli seminiferi], from whose epithelial lining the spermatozoa are formed. The tubules of each lobule converge to form a single, almost straight duct and these *tubuli recti* pass

Fig. 1018.—Diagram of the Testicular Tubules.



toward the mediastinum, where they open into the rete testis. In the lobules the seminiferous tubules are imbedded in a loose connective tissue that contains certain peculiar cells, the *interstitial cells*, to which has been attributed the formation of an internal secretion.

The **epididymis** (fig. 1017), which lies along the posterior border of the testis, is an elongated structure with a *body* [corpus epididymidis], enlarged above to form the *head* [caput] and to a less extent below to form the *tail* [cauda]. It is invested by a tunica albuginea, continuous with, but much thinner than that of the testis, and is formed mainly by the greatly contorted duct of the epididymis, which represents the beginning of the ductus deferens.

The head is formed by 12–14 tubules, the *efferent ducts* (fig. 1018), which take their origin from the rete testis as almost straight tubules, but gradually become greatly coiled, so that each duct has the form of an elongated cone, its coiled portion forming what is termed a *lobulus epididymidis*. At their coiled ends the various efferent ducts open into a single tube, the *ductus epididymidis*. Its diameter is only about 0.4 mm., but it measures 6.0–7.0 metres (18–21 feet) in its entire length, being coiled so extensively as to be contained within the body and tail of the epididymis. In this latter region it passes over into the ductus deferens.

Vessels.—The principal *artery* supplying the testis is the internal spermatic, from which branches are also sent to the epididymis. The deferential artery, a branch of the superior vesical, also sends branches to the epididymis and enters into extensive anastomoses with the testicular branches of the internal spermatic, and anastomoses also occur with the vessels supplying the scrotum. The *veins* correspond with the arteries. The *lymphatics* of the testis and epididymis unite to form four to six large stems which pass upward in the spermatic cord to terminate in the lower lumbar nodes.

Morphology.—The testis is primarily an abdominal organ and is developed in close relationship with the provisional kidney [mesonephros] whose duct, indeed, becomes the ductus deferens and some of whose tubules, becoming the efferent ducts, place the seminiferous tubules in communication with the ductus deferens. The epididymis may therefore be said to be developed from the mesonephros. The portions of this structure that are not concerned in the formation of the efferent ducts disappear for the most part; a few of the tubules persist, however, as rudimentary organs associated with the epididymis. Among these may be mentioned one or more blindly ending, coiled tubules, varying from 5–30 cm. in length, which are connected with the ductus epididymidis usually in the tail of the epididymis. They are known as the *ductuli aberrantes* (fig. 1018) and may be regarded as persistent excretory mesonephric tubules. Another of the rudimentary organs is the *paradidymis* (*organ of Giraldès*), which is a whitish body, situated immediately above the head of the epididymis, and is composed of irregularly coiled tubules, which terminate blindly at both extremities. They may be regarded as efferent ducts that have failed to connect with the testis and are of interest in that they sometimes develop into cysts connected with the epididymis.

In addition there is frequently attached to the upper pole of the testis a solid oval body composed of connective tissue, known as the *appendix testis* (*hydatid of Morgagni*) (fig. 1017). It measures from 3 to 8 mm. in length and its significance is doubtful. A similar, though smaller structure, the *appendix epididymidis*, is attached less frequently to the head of the epididymis. It is usually provided with a distinct stalk and contains a cavity; it is believed to represent the upper end of the Müllerian duct, present in the embryo and giving rise to the tuba uterina in the female, but almost completely degenerating in the male.

The testis begins its descent from the abdominal cavity into the scrotum at the third month of fetal life and reaches the abdominal inguinal ring at about the sixth month, but it is not until shortly before birth that it arrives at its final location in the scrotum. The cause of the descent is still uncertain, but it is supposed to be partly due to the failure of a band of connective tissue, which extends from the lower pole of the embryonic testis to the bottom of the scrotal pouch, to keep pace with the growth of the body walls. This ligament, which is known as the *gubernaculum testis*, thus becomes relatively shorter and draws the testis downward toward the point of its attachment to the scrotum. There are various features in the descent, however, that cannot be explained by the simple traction of the gubernaculum and it must be regarded as a complicated growth process whose meaning is yet uncertain. The gubernaculum testis apparently undergoes degeneration after the testis has reached its definitive location and cannot be recognized in connection with the adult testis.

Occasionally the descent of the testis is interrupted, the organ remaining either in the abdomen or in the inguinal canal. This condition of **cryptorchism** is always associated with a suppression of the function of the organ.

2. The Ductus Deferentes and Vesiculæ Seminales

Each **ductus deferens** is the continuation of a ductus epididymidis and extends from the tail of the epididymis to the prostatic portion of the urethra. At its beginning it ascends along the posterior border of the epididymis (*testicular portion*) and is at first slender and tortuous (fig. 1018), but before reaching the level of the head of the epididymis it becomes straighter and thicker (fig. 1017), owing to the development in its walls of strong layers of longitudinal and circular non-striated muscle tissue. Thence it is continued almost vertically upward as one of the constituents of the spermatic cord (*funicular portion*) to the subcutaneous inguinal ring, and, entering this, traverses the inguinal canal (*inguinal portion*), still forming a portion of the cord. At the abdominal ring it separates from the other constituents of the cord and, looping over the inferior epigastric artery near its origin, passes downward and backward over the lateral surface of the bladder (*pelvic portion*). At the junction of the posterior and lateral surfaces of the bladder it passes medially to the ureter and is then continued downward, forward and medially upon the base of the bladder until it reaches the prostate gland (fig. 1019), whose substance it traverses, as the *ductus ejaculatorius*, to open into the prostatic portion of the urethra (see p. 1263).

Just before it reaches the prostate gland each ductus deferens presents an irregular spindle-shaped enlargement, the *ampulla* (figs. 1019, 1020), whose walls are somewhat sacculated. Just beyond this it is joined upon its lateral surface by a club-shaped lobulated structure, the **vesicula seminalis** (fig. 1019). Each vesicle measures 4.5–5.5 cm. in length and has a greatest diameter of about 2 cm. It rests upon the posterior surface of the bladder, lying parallel with and lateral to the corresponding ductus deferens, and in its upper one-third is in relation posteriorly with the peritoneum which forms the anterior wall of the recto-vesical pouch, while below it is in contact with the anterior wall of the lower part of the rectum, through which it may be palpated. Indeed, the two vesiculæ, together with the ductus deferentes, form the lateral boundaries of the triangular area at the base of the bladder, throughout which that organ is in relation to the rectum.

Each vesicle is enclosed within a fine capsule of connective tissue, which contains numerous non-striated muscle fibres and is continuous below with the capsule of the prostate gland. On removing this capsule the vesicle will be found to consist of a greatly coiled tube, 10–12 cm.

FIG. 1019.—DUCTUS DEFERENTES AND VESICULÆ SEMINALES. (After Sappey.)

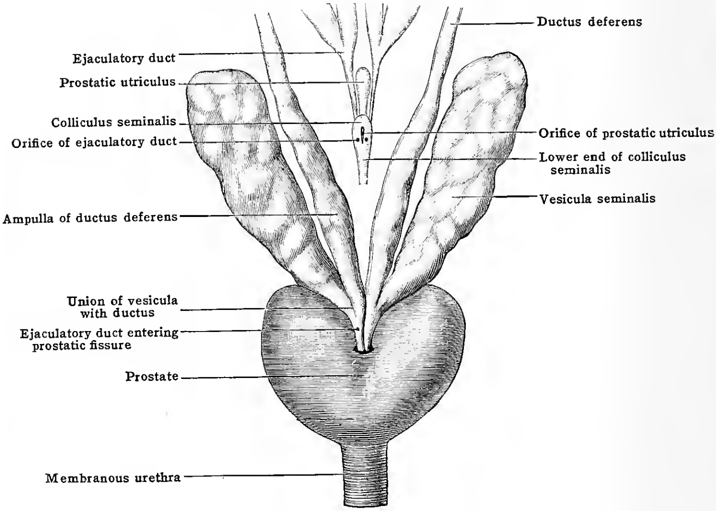


FIG. 1020.—DUCTUS DEFERENS AND VESICULA SEMINALIS DISSECTED. (After Sappey.)

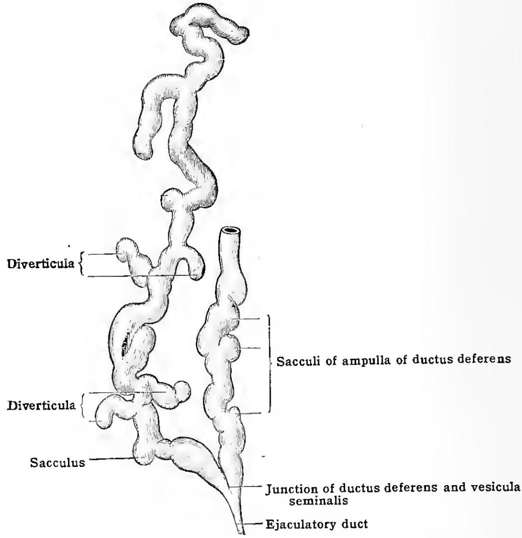
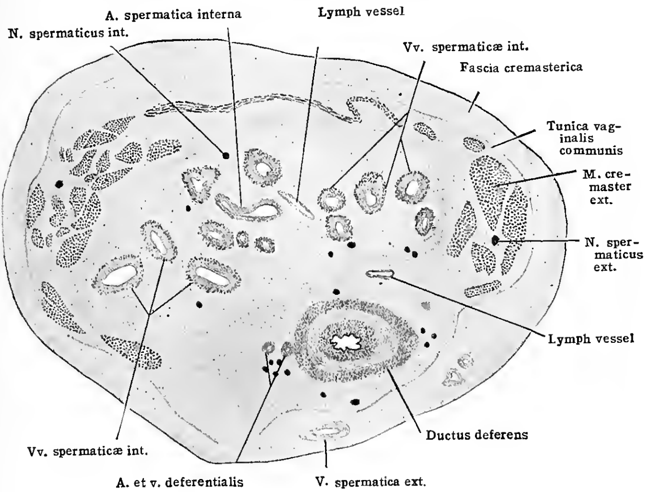


in length, which ends blindly and has attached to it on either side a number of short diverticula (fig. 1020). The walls of the tube and diverticula are formed of smooth muscle tissue, arranged in layers similar to those of the ductus deferentes, and are lined by a much folded mucous membrane, whose cells contain considerable quantities of a yellowish-brown pigment, and also contribute a secretion to the seminal fluid. In addition to having this function the vesiculæ also serve as receptacles for the spermatozoa. They arise as diverticula from the embryonic ductus deferens, and it is worthy of note that a number (4 or 5) of similar but quite small diverticula arise from the upper part of each ductus ejaculatorius.

Vessels and nerves.—The *artery* supplying the ductus deferens is the a. deferentialis, a branch of the superior vesical. It accompanies the ductus to the tail of the epididymis and also gives a branch to the vesicula seminalis. The latter also receives branches from the middle hæmorrhoidal and inferior vesical arteries. The deferential *vein* accompanies the ductus deferens to the base of the bladder where it breaks up into a plexus that communicates with the seminal venous plexus formed by the veins from the seminal vesicles. This joins with the vesical and pudendal plexus and so communicates with the hypogastric vein. The *lymphatics* of the ductus deferentes and seminal vesicles pass to the external iliac and hypogastric nodes. The *nerves* of both structures are derived from the hypogastric plexus.

The spermatic cord.—In its descent through the inguinal canal into the scrotum the testis necessarily drags after it the ductus deferens and the testicular vessels and nerves, these structures coming together at the abdominal inguinal

Fig. 1021.—Cross-section of the Spermatic Cord.



ring to form what is termed the *spermatic cord* [funiculus spermaticus]. This structure extends, therefore, from the abdominal inguinal ring, through the inguinal canal and the neck of the scrotal sack to the testis, and is enclosed within the same investing layers as the testis.

Thus as it emerges from the subcutaneous inguinal ring it receives an investment of connective tissue continuous with the intercrural fibres and the aponeurosis of the external oblique muscle. This cremasteric fascia has beneath it bands of striated muscle tissue, the *external cremaster muscle* (fig. 1021), especially developed on the posterior surface of the cord and continuous with the internal oblique muscle of the abdomen, and within these is an indistinct layer of connective tissue, the *tunica vaginalis communis*, which is received at the abdominal inguinal ring where it is continuous with the fascia transversalis.

Within the sheath thus formed there is a matrix of connective tissue, usually containing considerable amounts of fat and strands of non-striated muscle tissue, which form what is termed the *internal cremaster muscle (funicular portion)*, and imbedded in this connective tissue are the various essential constituents of the cord. These are as follows (figs. 1017, 1021): (1) the *ductus deferens*, occupying the posterior surface of the cord and having associated with it the deferential artery and veins and the deferential plexus of nerve fibres; (2) the *internal spermatic artery*, which occupies the axis of the cord and is surrounded by (3) the *internal spermatic veins*, which form a complicated network, known as the *pam-*

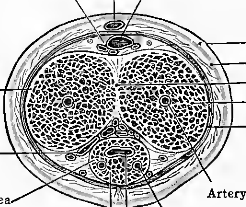
piniform plexus; (4) the *testicular lymphatics;* and (5) the *internal spermatic plexus* of nerves from the hypogastric plexus; and (6) branches of the *genito-femoral nerve* for the supply of the external cremaster muscles.

3. The Penis

The **penis** is composed of three rod-like bodies composed of erectile tissue (fig. 1023), firmly united together and invested by fascia and integument (fig. 1022). When this erectile tissue becomes engorged with blood the organ assumes an erect position, but otherwise it is pendulous, hanging downward in front of the scrotum from its attachment to the symphysis pubis. The erectile bodies are, however, prolonged backward beyond the symphysis pubis into the perineal region, and it is customary to speak of this perineal portion as the *root* of the penis [radix penis] or *pars fixa* in contrast to the *body* of the penis [corpus penis] or *pars libera.*

The **body of the penis** in its flaccid condition is almost cylindrical, but in erection it becomes somewhat triangular in section, what was the anterior surface or *dorsum penis** becoming flattened, while the opposite one, the *urethral surface* [facies urethralis], becomes more sharply rounded. At the free extremity of the penis there is a blunt conical enlargement, the **glans penis** (fig. 1023), at the apex of which is the external orifice of the urethra. The glans is separated from the body by a constriction, the *neck* [collum glandis], and from this region a fold of integument arises, which more or less completely encloses the glans, forming the *prepuce* [præputium] (fig. 1024). The prepuce is quite free from the glans dorsally but in the ventral mid-line it is attached to it, almost to the urethral

Fig. 1022.—Transverse Section through the Body of the Penis.



orifice, by a narrow line of adhesion, the *frenulum* [frenulum præputii], which contains blood-vessels of considerable size. The base of the glans has a well-marked rounded border, the *corona* [corona glandis], and is deeply concave for the reception of the distal ends of the corpora cavernosa penis.

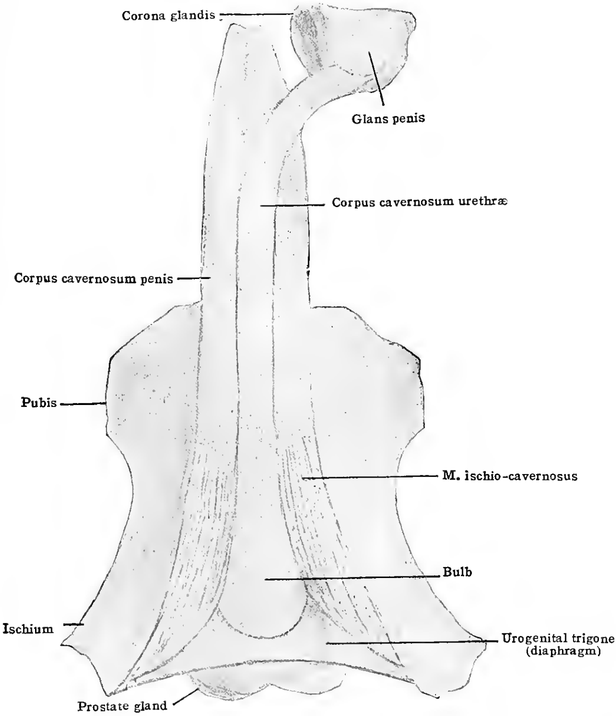
The **integument** of the penis is continuous with that of the scrotum and like it is pigmented and contains no fat. Immediately below it there is a layer of non-striated muscular tissue, the *dartos,* and beneath this a layer of loose connective tissue, containing the superficial vessels and nerves of the penis; beneath this again is a denser, elastic sheet of connective tissue, the *fascia penis* (fig. 1022), which encloses the erectile bodies as far as the base of the glans and is continuous with the superficial fascia of the perineum and inguinal region. Where it passes beneath the symphysis pubis it receives from the anterior surface of the latter a strong band of fibrous tissue, which forms the *suspensory ligament* of the penis [lig. suspensorium penis].

Two of the erectile bodies of the penis, the **corpora cavernosa penis,** are paired (fig. 1023). They are attached at their proximal ends to the base of the tuberosity of the ischium, and in this part of their extent are termed the *crura penis,* being

* It should be noted that the terms "dorsum" and "dorsal" are used for the penis in a sense directly opposite their usual meaning.

composed of fibrous connective tissue, which has resting upon it the m. ischio-cavernosus (see Section IV). The two **crura** are situated in the lateral portions of the superficial perineal interspace and pass forward parallel with the rami of the ischia and pubis, gradually becoming transformed into cavernous erectile tissue. Shortly before they reach the level of the symphysis pubis the two corpora come into contact in the median line, their medial walls fusing to form a *septum*, and thus united they extend throughout the entire length of the body of the penis, occupying the dorsal portion of the space enclosed by the fascia penis (fig. 1022). They terminate at the posterior surface of the glans, where they taper

Fig. 1023.—Dissection of the Perineum Showing the Structure and Relations of the Penis.



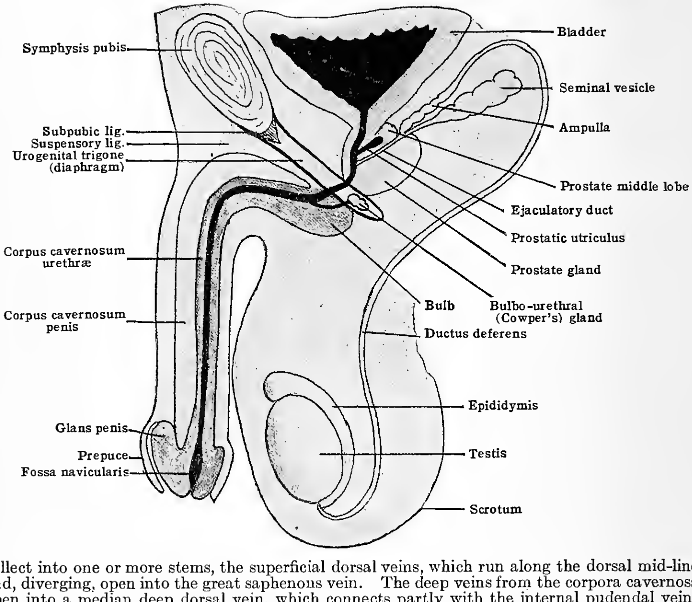
somewhat to be received into its basal concavity (fig. 1024). The septum in its proximal part forms a complete partition between the two bodies, but distally it is broken through by numerous clefts by which the blood lacunæ of the two bodies are placed in communication.

Each **corpus cavernosum penis** consists of a strong elastic fibrous sheath, the *tunica albuginea*, from which trabeculæ extend into the substance of the organ, dividing it into a network of communicating cavities, into which open terminal branches of the a. profunda penis, which traverses the axis of the corpus. These cavities consequently are to be regarded as vascular lacunæ, which, becoming engorged with blood, produce the enlargement and erection of the organ.

The third erectile organ is the **corpus cavernosum urethræ** (formerly "corpus spongiosum") (fig. 1023), so called because it is traversed throughout its entire length by the urethra (fig. 1024). It is an unpaired, median structure, having no bony attachments and begins posteriorly in the superficial perineal interspace with an enlargement, the **bulb** [bulbus urethræ] (fig. 1023), whose posterior surface rests on the superficial fascia of the urogenital trigone and is enclosed by the m. bulbo-cavernosus. Anteriorly the bulb gradually tapers to a rather slender cylindrical portion, the *body*, very uniform in diameter, which extends throughout the entire length of the body of the penis, lying in the median line beneath the fused corpora cavernosa penis (figs. 1022, 1023). At the neck of the penis it undergoes a sudden enlargement to form the *glans*, the whole of that structure, which has already been described, being formed by the corpus cavernosum urethræ. The structure of the corpus cavernosum urethræ is essentially the same as that of the corpora cavernosa penis, the tunica albuginea, however, being much thinner.

Vessels and nerves.—The principal *arterial* supply of the penis is derived from the internal pudendal artery (see p. 610), although the proximal portion of its integument is also supplied by the external pudendal branches of the femoral artery. The *veins* from the integument

FIG. 1024.—MID-SAGITTAL SECTION (DIAGRAMMATIC) SHOWING MALE BLADDER, URETHRA, ETC.



collect into one or more stems, the superficial dorsal veins, which run along the dorsal mid-line and, diverging, open into the great saphenous vein. The deep veins from the corpora cavernosa open into a median deep dorsal vein, which connects partly with the internal pudendal veins and partly with the pudendal plexus. Both the superficial and deep *lymphatics* terminate in the superficial inguinal nodes. The lymph-vessels from the glans are said to follow those of the urethra and end in the deep inguinal and external iliac nodes.

The *nerves* supplying the penis are the anterior scrotal branches of the ilio-inguinal and the perineal branches and dorsal nerve of the penis from the pudendal. Sympathetic fibres also pass to the penis from the hypogastric plexus and with these fibres from the third and fourth sacral nerves, which constitute what is termed the nervus erigens, since stimulation of it produces erection of the organ. An anatomical provision for the production of this phenomenon has been found in the occurrence of peculiar thickenings of the intima of the arteries of the penis, by which the lumina of the vessels are greatly diminished or even occluded when in a state of moderate contraction, as when the organ is flaccid. When the arteries are dilated the intimal thickenings become reduced in height and the blood is afforded a free passage into the lacunar spaces of the corpora cavernosa, which thus become engorged.

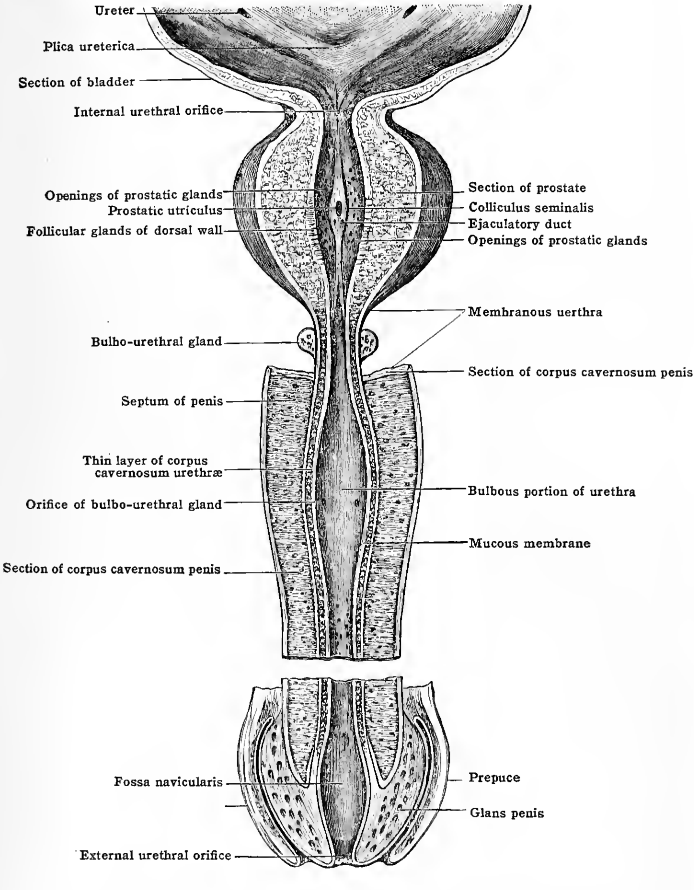
4. THE MALE URETHRA

The **urethra** is the canal which extends from the bladder to the extremity of the glans penis and serves for the passage of both the urine and the seminal fluid.

In its course (fig. 1024) it traverses first the prostate gland, then the urogenital diaphgram and then the entire length of the corpus cavernosum urethræ, and may thus be regarded as being composed of three portions.

The **prostatic portion** [pars prostatica] (fig. 1024) extends almost vertically downward from the neck of the bladder, traversing the substance of the prostate gland. In its proximal part there is on its posterior wall a median longitudinal ridge, the *crista urethralis*, which below dilates into an oval enlargement, the *colliculus seminalis* (figs. 1015, 1025), to accommodate which there is a marked

Fig. 1025.—The Male Urethra, cleft anteriorly to show the Mucous Coat.



widening of the lumen of the urethra in this part of its course. At the centre of the colliculus there is an elongated opening of a pouch of varying depth, termed the *utriculus prostaticus* ("uterus masculinus"), which corresponds to the lower part of the vagina in the female (see p. 1279). Situated one on either side of this are the much smaller openings of the *ejaculatory ducts*. Owing to the prominence formed by the colliculus a section of the urethra in this region is somewhat ∩-shaped, and at the bottom of the furrows on either side of the median elevation are the minute openings of the numerous ducts of the prostate gland (fig. 1025).

On its emergence from the prostate gland the urethra at once penetrates the deep layer of fascia of the urogenital trigone and enters the deep perineal interspace, this portion of its course being known as the **membranous portion** [pars membranacea]. Its direction is now downward and slightly forward, curving beneath the subpubic ligament, from which it is separated by a plexus of veins and by the fibres of the sphincter urethræ membranaceæ, which form an almost complete investment for it. The lumen of this part of the urethra is much narrower than that of the prostatic portion, and since it traverses the rather unyielding fasciæ of the urogenital trigone it is less dilatable than in other parts of its extent, with the exception of the external orifice.

Passing through the superficial layer of fascia of the urogenital trigone the urethra then enters the bulb of the corpus cavernosum urethræ (fig. 1024) and is invested throughout the remainder of its extent by this structure, whence this portion is known as the **cavernous portion** [pars cavernosa]. In its proximal part this lies in the superficial interspace of the perineum and passes almost directly forward; but more distally, where it enters the body of the penis, it accommodates itself to the position of that organ, which it traverses lengthwise, lying in the midline near its ventral surface (fig. 1022). Thus the proximal portion of the cavernous and the whole of the membranous and prostatic portions have a fixed position, whence they are sometimes associated as the *pars fixa* of the urethra, while the penial portion forms the *pars mobilis*. On entering the bulb the lumen of the urethra dilates somewhat and in this region has opening into it the ducts of the bulbo-urethral glands (fig. 1025), but as it enters the body of the corpus cavernosum it diminishes again and maintains a uniform diameter throughout the extent of that structure. When it reaches the glans penis it undergoes another dilation, which is known as the *fossa navicularis* (fig. 1025), beyond which it diminishes to the slit-like *external orifice*, situated at the extremity of the glans and forming the least dilatable portion of the entire urethral canal.

Throughout the greater part of its extent the cavernous portion of the urethra shows upon its dorsal wall the openings of numerous tubular depressions of the mucous membrane, the *urethral lacunæ* [lacunæ urethrales (Morgagnii)]. One of these, the *lacuna magna*, situated in the mid-dorsal line of the proximal part of the fossa navicularis, has its orifice guarded by a valve-like fold [valvula fossæ navicularis] of the mucous membrane and is sufficiently large to receive the point of a small catheter. Numerous minute glands [gl. urethrales] open upon the surface of the urethral mucosa. They are most abundant in the anterior wall, but occur also on the sides and floor.

Dimensions of the urethra.—The entire length of the urethra is somewhat variable in different individuals, the greatest variation being in the length of the pars mobilis. Of the pars fixa the prostatic portion is 2.5–3.0 cm. in length, the membranous portion about 1.0 cm., and the fixed part of the cavernous portion 6.5 cm., the entire pars fixa having thus a length of somewhat over 10.0 cm. (4 in.). The average diameter of the urethra is 5.0–7.0 mm., but it will be noted that the canal presents in its course three dilatations; namely, (1) at the fossa navicularis, which begins about 0.5 cm. from the external orifice; (2) the bulb of the corpus cavernosum urethræ; and (3) in the prostatic portion. Furthermore there are two regions in which it is distinctly narrowed; namely, at the external orifice and in the membranous portion. While the remaining portions are capable of considerable distention, these are relatively indistensible, the maximum diameter to which they may be dilated being about 10 mm. Arranged in an ascending order according to their capability for distention the parts would have the following order: external orifice, membranous portion, penial portion, prostatic portion, bulbar portion.

5. The Prostate Gland

The **prostate gland** [prostata] (figs. 1013, 1019, 1024 and 1025) is a mass of glandular and muscular tissue surrounding the proximal portion of the male urethra, and may, indeed, be regarded as a special development of the wall of this portion of the canal. It is a more or less flattened conical structure whose *base* [basis prostatæ] is in contact with the lower surface of the bladder and the *apex* [apex prostatæ] with the deep fascia of the urogenital trigone. Its *anterior surface* [facies anterior] is in relation with the symphysis pubis, from which it is separated by the pudendal plexus of veins, and *posteriorly* [facies posterior] it is separated from the lower portion of the rectum only by some loose connective tissue; laterally it is in relation with the levatores ani, receiving an investment from the endopelvic fascia covering these.

The *urethra* enters the base of the gland near its anterior border and traverses it almost vertically, so that the greater portion of the gland is posterior to the canal. On the posterior surface of the gland is a more or less distinct median vertical groove, which serves to separate the lateral portion as the *lateral lobes* [lobus dexter et sinister], although the demarcation is merely a superficial one. The groove terminates above in a well-marked notch on the posterior border of the base, and immediately in front of this there is a deep funnel-shaped depression of the surface, which receives the ejaculatory ducts. Beginning at this depression two grooves pass forward and slightly lateralward across the surface of the base, marking off a more or less pronounced median elevation, which constitutes what is termed the *middle lobe* [lobus medius] (fig. 1024); since this lies beneath the trigone of the bladder behind the internal orifice of the urethra its enlargement may produce more or less occlusion of the latter.

Dimensions.—The longest *axis* of the prostate, which is almost vertical in the erect posture measures 2.5–3.0 cm., the *transverse* diameter at the base is 4.0–4.5 cm. and the *thickness* 2.0–2.5 cm. Its *weight* is normally 20–25 grms. but in old age it may be double that, its dimensions having correspondingly increased.

Structure.—The prostate consists of some 15–30 branched tubular glands imbedded in a matrix of connective tissue, containing a large amount of non-striped muscle tissue and forming at the surface of the gland a strong fibro-muscular capsule from which prolongations are contributed to the pubo-vesical ligaments and muscles. The glands, which vary greatly in their development, are outgrowths from the mucous membrane of the urethra, into which their ducts open at the bottom of the grooves that lie lateral to the colliculus seminalis; similarly, the matrix with its muscle tissue is evidently the modified muscular coat of the urethra. Consequently there is no distinct demarcation between the wall of the urethra and the substance of the gland, and from the developmental standpoint the gland is to be regarded as the modified wall of the urethra.

The facts that the prostate shows a special development at puberty and undergoes more or less extensive degenerative changes with the cessation of the reproductive function, as seen in old age and in castrates, indicate that it is associated physiologically with the reproductive organs. Its secretion is a thin alkaline fluid, which may contain round or elongate, concentrically layered bodies, measuring 0.3–0.5 mm. in diameter and known as *amyloid bodies*, although they are really albuminous in chemical composition. They are constantly found in adults in the lumina of the glands and may become calcified. The secretion has been found to have a stimulating effect upon the spermatozoa, and this may be its principal function.

Vessels and nerves.—The *arterial* supply of the prostate is derived from the inferior vesical and middle hæmorrhoidal branches of the hypogastric artery. The *veins* form a rich prostatic plexus in the immediate vicinity of the gland, this being part of the general plexus at the base of the bladder and communicating posteriorly with the seminal plexus and anteriorly with the pudendal plexus. It drains finally into the hypogastric vein. The *lymphatics* are very abundant and form a network on the posterior surface of the gland from which four principal vessels pass to the hypogastric nodes. The *nerves* are derived from the hypogastric plexus.

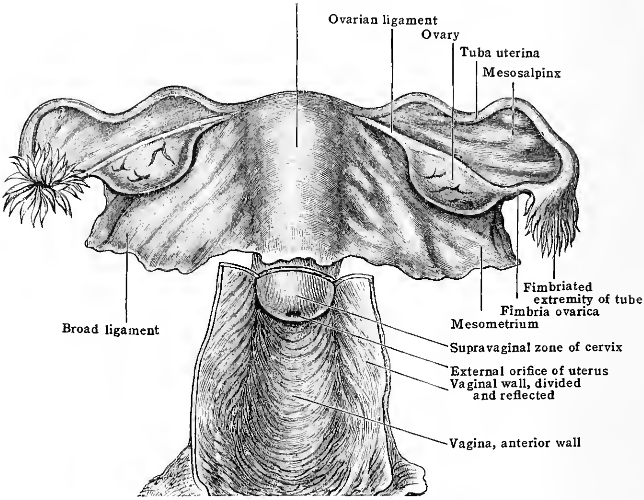
6. The Bulbo-urethral Glands

The **bulbo-urethral glands** [gl. bulbo-urethralis (Cowperi)] or **Cowper's glands** (figs. 1024, 1025) are two small tubulo-alveolar glands which lie one on either side of the membranous portion of the urethra, imbedded among the fibres of the sphincter urethræ membranaceæ, between the two layers of fascia of the uro-genital trigone. Each is a rounded body with a diameter of 4.0–9.0 mm. and is drained by a duct [ductus excretorius] which perforates the superficial fascia of the trigone and, entering the substance of the bulb of the corpus cavernosum urethræ, traverses it to open on the floor of the bulbar portion of the urethra after a total course of 3.0–4.0 cm. Nothing is definitely known as to the nature of the secretion or the functions of the glands.

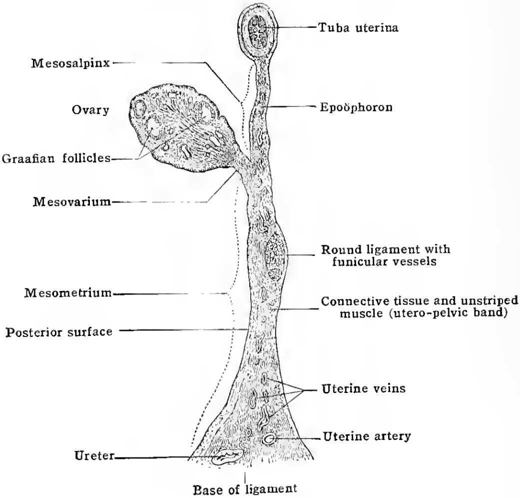
THE FEMALE REPRODUCTIVE ORGANS

The organs of reproduction in the female consist of (1) the *ovaries*, the essential organs of reproduction; (2) the *tubæ uterinæ* (Fallopian tubes), which serve as ducts for the conveyance of the ova to (3) the *uterus*, in which the embryo normally undergoes its development; (4) the *vagina*, a canal by which the uterus is placed in communication with the exterior; and (5) the *external genitalia*. In addition it will be necessary to consider here the female *urethra*, although it differs from that of the male in that it serves merely as a passage for the contents of the bladder and does not transmit the reproductive elements.

Fig. 1026.—The Female Organs of Generation. (Modified from Sappey.) (Vagina divided and laid open behind.)

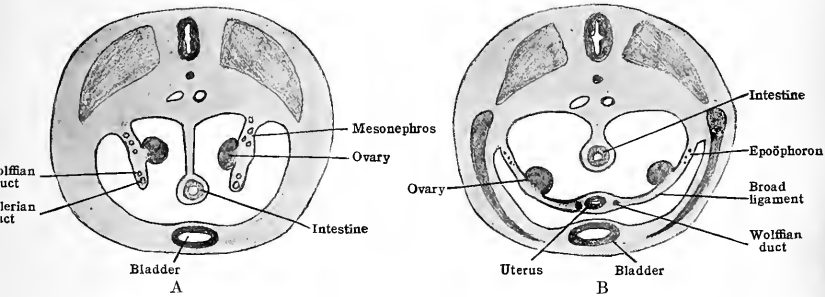


ig. 1027.—Diagrammatic Sagittal Section of the Broad Ligament.



Broad ligament.—The first three of these structures are entirely contained within the true pelvis and are associated with a transverse fold of peritoneum which rises from the floor of the pelvic cavity between the bladder and the rectum, incompletely dividing the cavity into an anterior and a posterior compartment. It is known as the *broad ligament* of the uterus [lig. latum uteri] (fig. 1026). The broad ligament appears to extend laterally from the sides of the uterus to the lateral walls and floor of the pelvis, although in reality it extends across the pelvic cavity from side to side and encloses the uterus between the two layers of which it is composed. It is attached to the floor of the pelvis below, where the two layers are reflected, the one upon the anterior wall of the pelvis and the posterior and superior surfaces of the bladder, and the other posteriorly over the floor of the pelvis to the posterior pelvic wall and the rectum, forming the anterior wall of a deep depression between the rectum and uterus, known as the *recto-uterine pouch* (*of Douglas*) [excavatio rectouterina (cavum Douglasi)] (fig. 1035). Its lower border also passes upward upon the sides of the pelvis, resting upon the pelvic fascia, but its lateral borders are free, extending between the lateral wall of the pelvis and the extremity of the tuba uterina on each side and forming what are termed the *infundibulo-pelvic ligaments*. The upper border is also free and contains the tuba uterina on either side, and the fundus of the uterus in the midline (fig. 1027).

Fig. 1028.—Cross-sections of the Body Illustrating the Development of the Female Urogenital system. A, at Higher Level. B, at Lower Level.



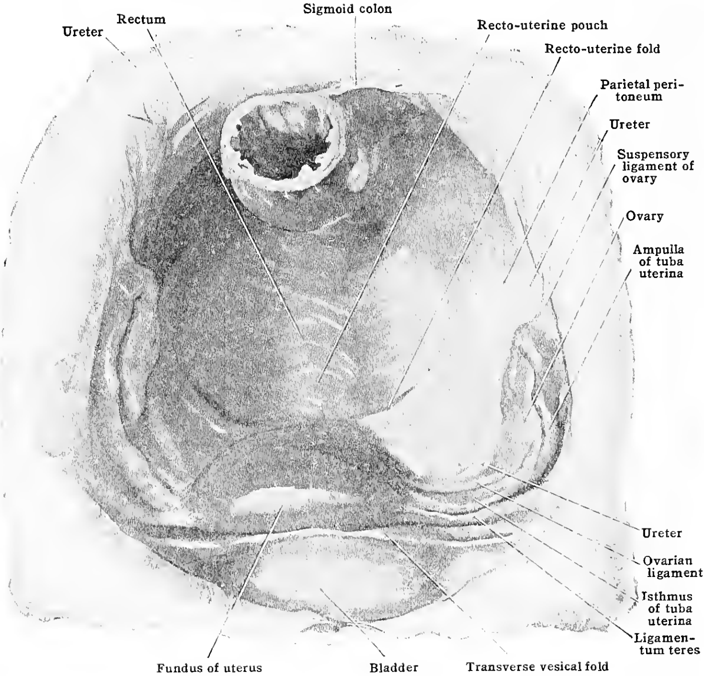
Attached to the posterior layer of the broad ligament a little below its upper border and therefore projecting into the posterior compartment of the pelvis, there is a horizontal shelf, termed the **mesovarium,** since it has the ovary attached to its free edge (fig. 1027). The portion of the broad ligament above this is known as the **mesosalpinx** (salpinx=tuba), while that below is termed the **mesometrium** (metra=uterus). The remaining structures that occur between the two layers of the broad ligament will be described with the organs with which they are associated, but it is to be noted that the ligament in its upper part is broader than the transverse diameter of the pelvic cavity and its sides are accordingly folded back upon the lateral walls of the cavity, following the course of the tuba uterina.

The broad ligament is the adult representative of the fold of peritoneum which encloses the embryonic excretory organ, the mesonephros. This is for a time a voluminous organ, projecting under cover of the peritoneum from the dorsal wall of the abdomen and bearing upon its medial wall a thickening, the **genital ridge** (fig. 1028 A), from which the reproductive gland develops. In the free edge of the peritoneum enclosing it two ducts occur, the **Wolffian duct,** which is the duct of the excretory organ and becomes the ductus deferens of the male, and the **Müllerian duct.** With the progress of development the two Müllerian ducts fuse in the lower portions of their course to form the uterus and vagina (prostatic utriculus of the male), while in their upper parts they remain separate and form the tubæ uterinæ. By this fusion the two peritoneal folds are brought into continuity at their edges, and (the mesonephros degenerating on the formation of the permanent kidney) constitute the broad ligament (fig. 1028 B). This structure therefore contains between its two layers the uterus and the remains of the mesonephros, and has the ovary attached to its posterior surface. In the male what corresponds to the broad ligament fuses with the peritoneum covering the posterior surface of the bladder.

1. The Ovaries

Form and position.—The *ovaries* [ovaria] are two whitish organs, situated one on either side of the pelvic cavity. Each has somewhat the shape of an almond (fig. 1026). It is attached by one of its edges [margo mesovaricus] to the border of the mesovarium, and since it is along this line of attachment that the vascular and nerve supply enters the substance of the organ, this border is spoken of as the *hilus* [hilus ovarii]. The opposite border is free [margo liber]. The larger rounded end is directed toward the free extremity of the tuba uterina and hence is known as the *tubal extremity* [extremitas tubaria], while the other, the *uterine extremity* [extremitas uterina], is directed toward the uterus; the two surfaces, owing to their topographic relations, are known as the *lateral* and *medial surfaces* [facies medialis et lateralis].

Fig. 1029.—The Female Pelvic Organs Viewed from Above. (Spalteholz.)



The exact position of the ovary in the pelvis is subject to some variation, but typically it lies almost in a sagittal plane (fig. 1029) against the lateral wall of the pelvis, resting in a distinct depression, the *fossa ovarica*, lined by peritoneum and bounded above by the external iliac vessels and behind by the ureter and uterine artery, while beneath its floor are the obturator vessels and nerve. The long axis of the ovary is almost vertical when the body is erect, the tubal pole being upward; the mesovarial border is directed forward and laterally, its free border dorsally and medially while its surfaces look almost laterally and medially.

Frequently, however, the uterus is displaced to one side, dragging the uterine extremity of the opposite ovary (by the attachment of the ovarian ligament) toward the mid-plane. The long axis of the ovary thus becomes oblique, approaching more or less the horizontal. The ascending portion of the tuba uterina rests upon its mesovarial border and the fimbriated mouth of the tube is in contact with its medial surface. When enlarged the ovary may be felt through lateral wall of the vagina and, better, through that of the rectum; and its position with regard to the surface may be indicated by a point midway between the anterior superior spine of the ilium and the symphysis pubis or the opposite pubic tubercle.

The position assumed by the ovary is due to its attachment to the edge of the mesovarium and to the upper portion of the broad ligament being broader than the diameter of the pelvis, so that it is folded back upon the lateral walls of the cavity. In addition to its attachment to the broad ligament through the mesovarium, the ovary is also connected to the side of the uterus by the *ovarian ligament* [lig. ovarii proprium] (fig. 1026), a band of connective tissue with which numerous non-striped muscle fibres are intermingled. It lies between the two layers of the broad ligament, on the boundary line between the mesosalpinx and the mesometrium, and extends from the uterine pole of the ovary to the side of the uterus. Here it is attached just below the origin of the tuba uterina and above the point of attachment of the round ligament of the uterus, with which it is primarily continuous. Another ligament, termed the *suspensory ligament* of the ovary (figs. 1029, 1034), extends laterally between the two layers of the broad ligament from the tubal extremity of the ovary to the pelvic walls, forming the lateral portion of the lower boundary of the mesosalpinx. It is formed by the vessels and nerves (internal spermatic) passing to and from the ovary, and from the point where it meets the lateral pelvic wall it may be traced upward for some distance upon the posterior wall of the abdomen, behind the peritoneum, which it elevates into a more or less distinct fold, whose lateral wall on the right side becomes continuous above with the peritoneum lining the subcœcal fossa.

Size.—The *size* of the ovary varies considerably, that of the right side being as a rule somewhat larger than that of the left. The length may be anywhere from 2.5 cm. to 5.0 cm., the breadth about half the length and the thickness half the breadth. Its average weight in the adult is from 6.0 to 8.0 grms., but in old age it may fall to 2.0 grms.

Structure.—The ovary is covered by a layer of columnar epithelium which is continuous with the peritoneal epithelium along the line of the attachment of the mesovarium; the ovary consequently is not covered by peritoneum, but is rather to be regarded as a local thickening of the peritoneum. Its substance is a network of connective tissue, in which non-striped muscle fibres also occur, and is known as the *stroma*. The more central portions of this are largely occupied by blood-vessels but in the cortical portions are multitudes of immature ova, surrounded by their follicle cells [folliculi oophori primarii]; and also numbers of cavities of various sizes, lined with follicle cells and filled with fluid, each containing an ovum [ovulum] in a more or less advanced stage toward maturity. These are the *Graafian follicles* [folliculi oophori vesiculosi (Graafi)], and as they ripen they increase in diameter and approach the surface, upon which they may form marked prominences. When mature the follicles burst, allowing the escape of the ovum, scars being thus formed upon the surface of the ovary that are known as *corpora albicantia*. If, however, the ovum becomes fertilized and pregnancy results the walls of the follicle undergo a remarkable development, forming what is known as a *corpus luteum*.

Epoöphoron and paroöphoron.—Closely associated with the ovaries are two rudimentary organs situated between the layers of the mesosalpinx and representing remains of the mesonephros of the embryo. The larger of these is the *epoöphoron* (fig. 1030). It consists of a longitudinal duct [ductus epoöphori longitudinalis (Gartneri)], lying parallel with the tuba uterina and closed at either extremity, and 10–15 transverse ducts [ductuli transversi], which open into the longitudinal duct. It is the remains of the upper or reproductive portion of the mesonephros and therefore is the homologue of the epididymis of the male. In addition there is frequently to be found in the neighbourhood of the epoöphoron and close to the mouth of the tuba uterina one or more stalked, oval cysts, the *appendices vesiculosi* (*hydatids of Morgagni*), which may reach the size of a small pea.

The other organ is the *paroöphoron;* it is much smaller than the epoöphoron and usually disappears before adult life, but when present consists of a small group of coiled tubules, more or less distinct, representing a portion of the excretory portion of the mesonephros. Its equivalent in the male is therefore the paradidymis.

Vessels and nerves.—The chief *artery* is the ovarian, which together with the ovarian veins and lymphatics passes to the ovary in the suspensory ligament. An additional blood supply is furnished by the ovarian branch of the uterine artery. The *veins* follow the course of the arteries. As they emerge from the hilus they form a well-developed plexus (*pampiniform plexus*) between the layers of the mesovarium. Unstriped muscle fibres occur in the meshes of the plexus and the whole structure has much the appearance of erectile tissue. The *lymphatics* accompany the blood-vessels and terminate in the lumbar nodes. *Nerves* pass to the ovary with the ovarian artery from the renal and aortic sympathetic plexus.

2. The Tubæ Uterinæ

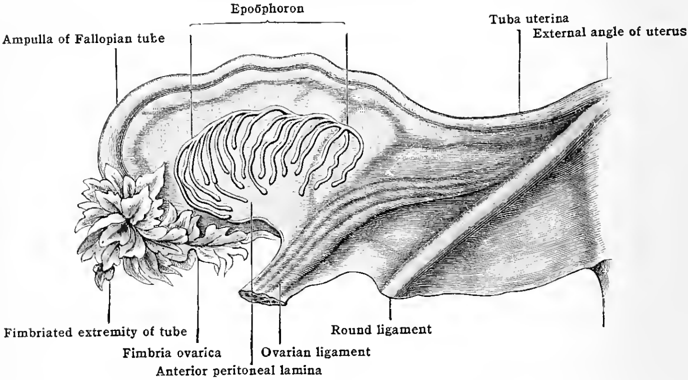
The **tubæ uterinæ** or **Fallopian tubes** (figs. 1026, 1030) serve to convey the ova to the uterus. They are two trumpet-shaped tubes, structurally continuous

Ductless Glands
Skin

with the superior angles of the uterus and running in the superior border of the broad ligament (mesosalpinx) to come into relation with the ovaries at their distal extremities. Each tube opens proximally into the uterine cavity and distally communicates with the pelvic portion of the peritoneal cavity by a funnel-shaped mouth, the **ostium abdominale,** which under normal conditions is closely applied to the surface of the ovary, so as to receive the ova as they are expelled from the Graafian follicles. Each tube is from 7 to 14 cm. in length and consists of a narrow straight portion, the **isthmus,** immediately adjoining the uterus, followed by a broader, more or less flexuous portion, the *ampulla,* which terminates in a funnel-like dilatation, the **infundibulum.** The margins of the infundibulum are fringed by numerous diverging processes, the **fimbria,** one of which, the **fimbria ovarica,** is much longer than the rest and extends along the free border of the mesosalpinx (the infundibulo-pelvic ligament) to reach the tubal pole of the ovary.

The course of each tube is at first almost horizontally laterally and backward from its attachment to the uterus, until it reaches the lateral wall of the pelvis and there comes into relation with the uterine extremity of the ovary (figs. 1029, 1034). It then bends at right angles and passes almost vertically upward

Fig. 1030.—The Broad Ligament and its Contents, seen from the Front. (After Sappey.)



along the mesovarial border of the ovary until it reaches its tubal extremity, where it curves downward and backward so that the mouth of the infundibulum and the fimbriæ rest upon the medial surface of the ovary.

Structure.—The tubæ occupy the upper free edge of the mesosalpinx and are therefore enclosed within a *peritoneal covering* [tunica serosa] except a small strip along their lower surface (fig. 1027), and hence a rupture of one of them may lead to the escape of its contents either into the peritoneal cavity or into the subserous areolar tissue between the two layers of the broad ligament. At the margins of the infundibulum and the borders of its fimbriæ the peritoneal epithelium becomes directly continuous with the mucous membrane lining the interior of the tube. The *subserous areolar* tissue [tunica adventitia] in the immediate vicinity of the tube is lax and contains the blood-vessels and nerves by which the tube is supplied; it forms a loose connection between the peritoneum and the *muscular wall* [tunica muscularis] of the tube. This consists of two layers of non-striped muscle fibres, an outer longitudinal and an inner circular one, and reaches its greatest development toward the uterine end of the tube. The inner layer [tunica mucosa] of the tube is lined by a columnar ciliated epithelium which is raised into numerous folds, simple in the region of the isthmus, but becoming higher and more complex in the ampulla, where, in transverse sections, the lumen seems to have a labyrinthine form. The beat of the cilia is toward the uterus.

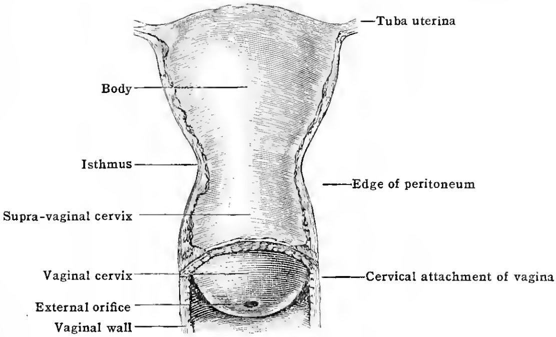
Vessels and nerves.—The *arteries* of the tubæ are derived from the ovarian and uterine, each of which gives off a tubal branch, which pass between the two layers of the mesosalpinx, the one medially and the other laterally, and anastomose to form a single stem. The *veins* accompany the arteries. The *lymphatics* accompany those from the ovary and fundus uteri and terminate chiefly in the lumbar nodes. The *nerves* of the ampulla are given off from the branches passing to the ovary, while those of the isthmus come from the uterine branches.

3. The Uterus

The **uterus** (fig. 1031) is an unpaired organ, situated between the two layers of the broad ligament and communicating above with the tubæ uterinæ and below with the vagina. It is pyriform in outline, although flattened antero-posteriorly (fig. 1032) and it is divided into two main portions, the **body** [corpus uteri] and the **cervix** by a transverse constriction, the **isthmus.**

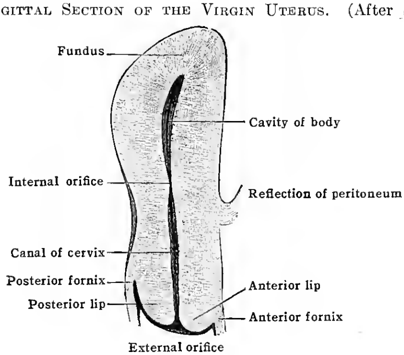
The **body** is the portion above the isthmus and in adults, especially in women

Fig. 1031.—The Posterior Surface of the Uterus. (After Sappey.)



who have borne children, is much larger than the cervix, although the reverse is the case in children. In young girls the two parts are about equal in size. The **anterior** or *vesical surfacc* [facies vesicalis] is almost flat (fig. 1032), while the **posterior** or *intestinal surface* [facies intestinalis] is distinctly convex, the two surfaces meeting in well-marked rounded borders, at the upper extremities of which the tubæ uterinæ are attached. The superior border which extends between the points of attachment of the two tubæ is thick and rounded and forms

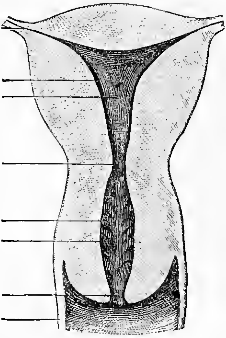
Fig. 1032.—Sagittal Section of the Virgin Uterus. (After Sappey.)



what is termed the *fundus uteri.* The *cavity* [cavum uteri] of the body is reduced to a fissure by the antero-posterior flattening of the walls and has a triangular form (fig. 1033), broad above where it communicates on either side with the cavity of a tuba uterina and narrow below where it communicates with the cavity of the cervix, this communication, which corresponds in position with the isthmus, forming what is known as the *internal orifice* [orificium internum] (internal os uteri).

The **cervix** is more cylindrical in form, though slightly expanded in the middle of its length, and is divided into a *supravaginal* [portio supravaginalis] and a *vaginal portion* [portio vaginalis] by the attachment to it of the vagina (fig. 1031). The line of this attachment is oblique, about one-third of the anterior surface of the cervix and about one-half of the posterior surface belonging to the vaginal portion. At the lower extremity of the cervix is the *external orifice* [orificium externum] (external os uteri), which is round or oval before parturition has taken place and is bounded by two prominent *labia*, anterior and posterior, the anterior one [labium anterius] being shorter and thicker than the posterior [labium posterius] and reaching a lower level (fig. 1032). In women who have borne children the external orifice assumes a more slit-like form and the labia become notched and irregular. The cavity of the cervix, known as the *canal of the cervix* [canalis cervicis], is fusiform in shape, and extends from the internal to the external orifice. On its anterior and posterior walls are folds known as the *plicæ palmatæ* (fig. 1033), consisting of a median longitudinal ridge from which shorter elevations extend laterally and slightly upward; these are most distinct in young individuals and are apt to become obliterated by parturition.

Fig. 1033.—Frontal Section of the Virgin Uterus. (After Sappey.)



Position and relations.—The direction of the axis of the uterus is apparently variable within considerable limits, not only in different individuals, but also in any one individual in correspondence with the degree of distention of the bladder anteriorly and the rectum posteriorly. In what may be regarded as the typical condition (fig. 1034) the external orifice lies at about the level of the upper border of the symphysis pubis and in the plane of the spines of the ischia. From this point the axis of the cervix is directed upward and slightly forward, the lower level of the anterior labium being thus brought about. The entire uterus is, accordingly, anteverted, and, furthermore, the body is bent forward (anteflexed) upon the cervix at the isthmus, the axis of the two portions making an angle, open anteriorly, of from 70° to 100°. Frequently, also, the body is slightly inclined either to the right or to the left.

The anterior surface of the uterus rests upon the upper and posterior surfaces of the bladder (fig. 1029), from which the body is separated by the utero-vesical pouch of peritoneum. The anterior layer of the broad ligament as it passes over the anterior surface of the uterus forms the posterior wall of this pouch and is reflected forward to the superior surface of the bladder at about the level of the isthmus (fig. 1034), so that the whole of the anterior wall of the cervix is below the floor of the pouch and is separated from the posterior surface of the bladder only by connective tissue. Posteriorly, however, the peritoneal covering of the uterus, which here forms the anterior wall of the recto-uterine pouch, extends down as far as the uppermost portion of the vagina and consequently invests the entire surface of the uterus, whose convex posterior wall is thus separated from the rectum by the recto-uterine pouch (figs. 1029, 1035). Coils of the small intestine rest upon the posterior surface of the body and may also be interposed between the cervix and the rectum. An important relation is that of the ureters to the cervix, these ducts, as they pass to the bladder, running parallel with the cervix at a distance of from 8 to 12 mm. from it.

Ligaments.—The *broad ligament* between whose layers the uterus is situated has already been described (p. 1267). In addition there is attached to each border

Fig. 1034—Mid-sagittal Section of the Female Pelvis (Spalteholz.)

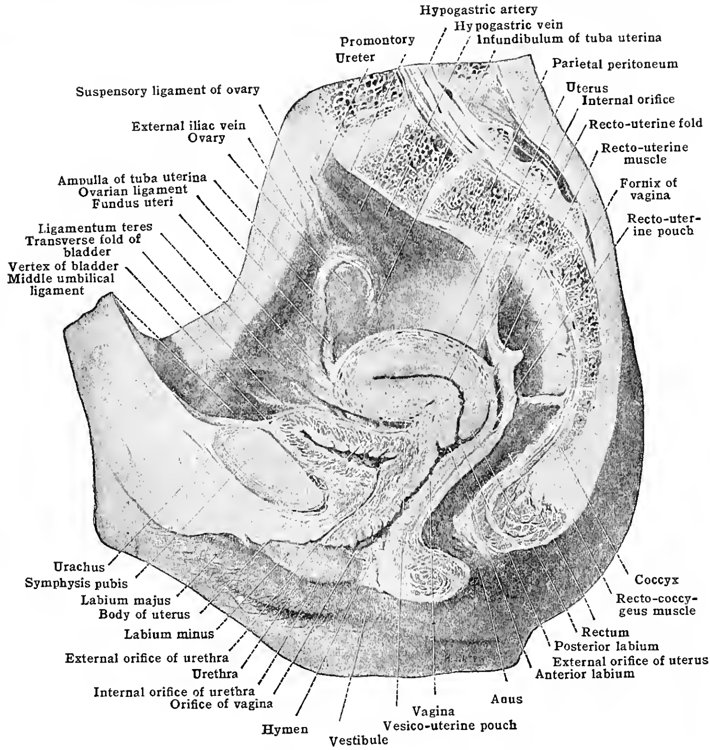


Fig. 1035.—Section of the Pelvis showing the Ligaments of the Uterus.

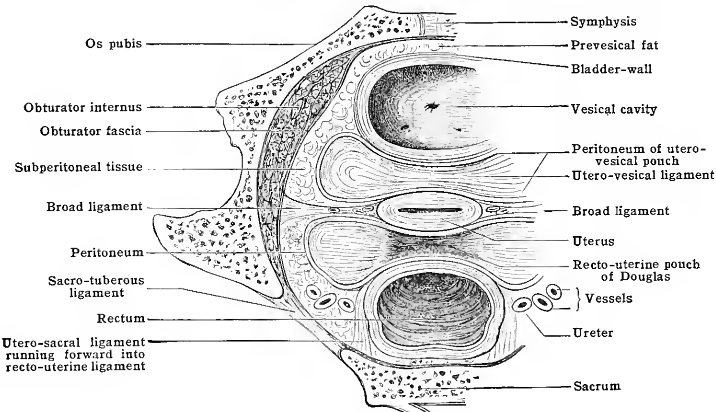


of the uterus, immediately below the point of attachment of the ovarian ligament, the *ligamentum teres* (round ligament) (fig. 1030), which is a fibrous cord containing non-striped muscle tissue. It extends downward, laterally and forward between the two layers of the mesometrium toward the abdominal inguinal ring, and, traversing this and the inguinal canal, it terminates in the labium majus by becoming continuous with its connective tissue.

It is accompanied by a funicular branch of the ovarian artery and a branch from the ovarian venous plexus, and in the lower part of its course by a branch from the inferior epigastric artery, over which it passes as it enters the abdominal ring. In its course through the inguinal canal it is accompanied by the ilio-inguinal nerve and the external spermatic branch of the genito-femoral.

The *utero-sacral ligaments* are flat fibro-muscular bands which extend, one on each side, from the upper part of the cervix uteri to the sides of the sacrum opposite the lower border of the sacro-iliac articulation. They produce the *recto-uterine folds* (fig. 1029) of peritoneum, which form the lateral boundaries of the mouth of the recto-uterine pouch (of Douglas) and their muscle fibres [m. rectouterinus] are continuous at one extremity with the muscular tissue of the uterus and at the other with that of the rectum.

Structure.—The portion of the broad ligament that invests the uterus forms the serous covering [tunica serosa] of the organ and is sometimes termed the *perimetrium*. Over the fundus and the greater portion of the body it is thin and firmly adherent to the subjacent muscular substance of the uterus, so that it cannot readily be separated from it. Over the posterior surface of the cervix and the lower part of the anterior surface of the body, however, it is thicker, and is separated from the muscular substance by a layer of loose connective tissue, the *parametrium*, which also extends upward along the sides of the uterus between the two layers of the broad ligament, with whose subserous areolar tissue it is continuous. Owing to this disposition of the parametrium the whole of the cervix may be amputated without encroaching upon the peritoneal cavity.

The main mass of the uterus is formed by the muscle tissue [tunica muscularis] or *myometrium*, whose fibres have a very complicated arrangement. Two principal layers may be distinguished, an outer, weak one, composed partly of longitudinal fibres continuous with those of the tubæ uterinæ, and of the round and utero-sacral ligaments, and a much stronger inner one, whose fibres run in various directions and have intermingled with them in the body of the uterus large venous plexuses. The inner surface of the myometrium is lined by a mucous membrane [tunica mucosa] or *endometrium*, which has a thickness of from 0.5 to 1.0 mm. and is composed of tissue resembling embryonic connective tissue, bearing upon its free surface a single layer of ciliated columnar epithelium. On account of its structure the tissue is rather delicate and friable, and numerous simple tubular glands, which open into the cavity of the uterus, traverse its entire thickness. In the cervix the mouths of some of the glands may become occluded, producing retention cysts, which appear as minute vesicles projecting from the surface between the plicæ palmatæ; they are known as *ovula Nabothi*, after the anatomist who first described them.

Vessels and nerves.—The principal *artery* of the uterus is the uterine, whose terminal portion ascends along the lateral border of the uterus in a tortuous course through the parametrium, giving off as it goes lateral branches to both surfaces of the uterus. Above, it anastomoses with the ovarian artery, which thus forms an accessory source of blood supply during pregnancy. The *veins* form a plexus that is drained by the ovarian and uterine veins, a communication with the inferior epigastric being also made by way of the vein accompanying the round ligament. The *lymphatics* from the greater portion of the body pass to the iliac nodes: those of the fundus accompany the ovarian vessels to the lumbar nodes. A vessel also accompanies the round ligament to terminate in one of the superficial inguinal nodes. The lymph-vessels from the cervix terminate in the external iliac, hypogastric and lateral sacral nodes.

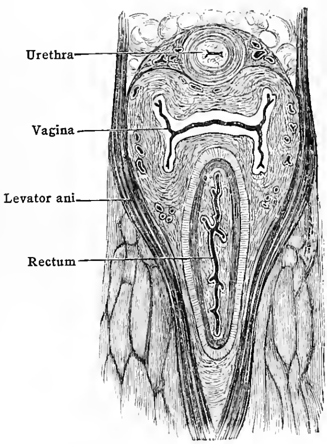
The *nerves* of the uterus pass to it from two sympathetic ganglia, situated one on either side of the cervix, whence they are termed the cervical ganglia, and forming part of the *plexus utero-vaginalis*. Branches pass to the ganglia from the hypogastric plexus and also from the second, third and fourth sacral nerves.

4. The Vagina

The **vagina** (fig. 1034) is a muscular, highly dilatable canal lined by mucous membrane, and extends from the uterus to the external genitalia, where it opens to the exterior. Its long axis is practically parallel with that of the lower part of the sacrum and it therefore meets the cervix uteri at a wide angle which is open anteriorly. Its anterior wall is, accordingly, somewhat shorter than the posterior, measuring 6.0–7.0 cm., while the posterior one is about 1.5 cm. longer. It becomes continuous with the cervix uteri some distance above the lower extremity of that structure, which thus projects into the lumen of the vagina, and there is so formed a narrow circular space between the wall of the vagina and the vaginal portion of the cervix uteri. The roof of the space is formed by the reflection of the vagina upon the cervix and is termed the *fornix*. Owing to the greater length of the posterior wall of the vagina the portion of the circular space below the posterior fornix is considerably deeper than that below the anterior.

In its ordinary condition the lumen of the vaginal canal is a fissure, which in transverse section resembles the form of the letter H with a rather long transverse bar (fig. 1036). On both the anterior and the posterior wall there is in the median line a well-marked longitudinal ridge, the *columna rugarum*, which is especially distinct in the lower part of the anterior wall, where it lies immediately beneath the urethra and forms what is known as the *urethral carina*. From both columnæ other ridges pass laterally and upward on either side, forming the *rugæ vaginales*. Both these and the columnæ diminish in distinctness with advance in age and with successive parturitions. Toward its lower end the vagina traverses the urogenital trigone, being much less dilatable in this region than elsewhere, and it opens below into the vestibule of the external genitalia. Its orifice is partially closed by a fold of connective tissue, rich in blood-vessels, and lined on both surfaces by mucous membrane. This membrane, known as the

Fig. 1036.—Horizontal Section of Vagina and adjacent Structures. (After Henle.)



hymen, has usually a somewhat semilunar form, surrounding the posterior border of the orifice, but it may take the form of a circular curtain pierced by one or several apertures.

It varies greatly in strength and development and although it is nearly always ruptured by the first act of sexual congress, it may remain unbroken until parturition. Rarely it takes the form of a complete imperforate curtain and may necessitate a surgical operation at the commencement of the menstrual periods. After rupture the remains of the hymen persist as small lobed or wart-like structures, the *carunculæ hymenales*, around the vaginal orifice.

Relations.—The uppermost part of the posterior wall of the vagina is in relation with the peritoneum forming the floor of the recto-uterine pouch (of Douglas), but elsewhere the canal is entirely below the floor of the peritoneal cavity. Posteriorly it rests almost directly upon the rectum (fig. 1036), and the contents of that viscus may be readily felt through its walls. *Anteriorly* it is in intimate relation with the urethra and the posterior wall of the bladder (figs. 1034, 1036), while *laterally* it is crossed obliquely in its upper third by the ureters as they pass to the base of the bladder, and in its lower two-thirds by the edges of the anterior portion of the levatores ani. The *duct of Gärtner*, the remains of the lower portion of the Wolffian duct, may occasionally be found at the side of the upper half of the vagina as a minute tube or fibrous cord. The external orifice is surrounded by the fibres of the bulbo-cavernosus muscle, which may be regarded as forming a sphincter (*sphincter vaginæ*).

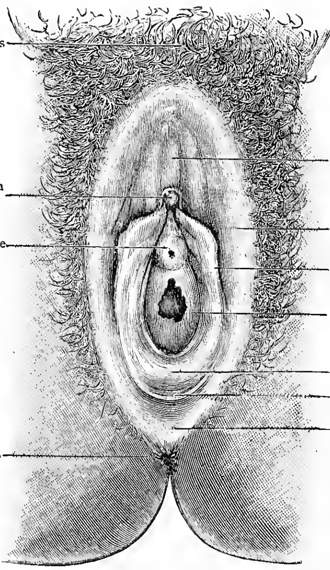
Structure.—The wall of the vagina is formed mainly of non-striped muscle tissue, whose fibres are indistinctly arranged in two layers, an outer longitudinal and a less distinct inner circular one. Above, this tissue is continuous with that of the cervix uteri, as is also the mucous membrane which lines the lumen. This differs from that of the cervix in having a stratified squamous epithelium and in being destitute of glands.

Vessels and nerves.—The *arteries* of the upper part of the vagina are derived from the vaginal branch of the uterine; its middle portion is supplied by a vaginal branch from the inferior vesical and its lower part by the middle hæmorrhoidal and internal pudendal. The *veins* form a rich plexus on the surface and drain into the hypogastric vein. The *lymphatics* are very numerous and drain for the most part to the hypogastric and lateral sacral nodes; some of those from the lower portion of the canal joining with those from the external genitalia to pass to the inguinal nodes. The *nerves* passing to the vagina are derived from the utero-vaginal and vesical plexuses.

5. The Female External Genitalia and Urethra

The female **external genitalia** [pudendum muliebre] (vulva) present an elongated depression, occupying the entire perineal region and bounded laterally by

Fig. 1037.—The External Genitals of the Female.



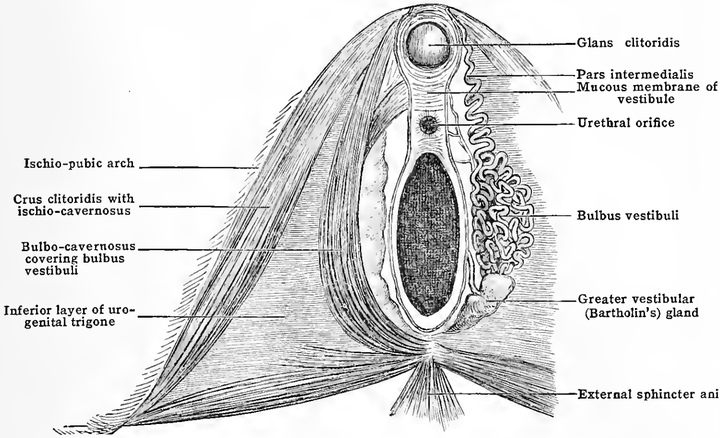
two folds of integument, the *labia majora* (fig. 1037). These anteriorly are continued into the *mons pubis*, an eminence of the integument over the symphysis pubis due to a development of adipose tissue. The medial surfaces of the two labia are normally in contact, the fissure between them being termed the *rima pudendi*, and where they meet anteriorly and posteriorly they form the *anterior* and *posterior commissures* [commissura labiorum anterior et posterior]. Just anterior to the latter is an inconstant transverse fold, the *frenulum labiorum pudendi* ("fourchette") (fig. 1037). The mons and the outer surfaces of the labia are covered by short crisp hairs, but the medial surfaces of the labia are smooth, possessing only rudimentary hairs, but beset with large sebaceous and sudoriparous glands. The interior of the labia is occupied by a mass of fat tissue in which the distal extremity of the round ligament of the uterus breaks up.

Within the depression bounded by the labia majora is a second pair of integumental folds, the *labia minora* (fig. 1037), which differ from the labia majora in being destitute of hairs and fat. They are usually concealed by the labia majora, but are sometimes largely developed and may then project through the rima pudendi, assuming a dried and pigmented appearance.

The labia minora divide and unite anteriorly over the distal extremity of the clitoris, forming the *præputium clitoridis* in front of the clitoris, and the *frenulum clitoridis* behind it. Posterior to this they diverge and reach their greatest height, gradually diminishing as they pass backward to terminate in a slight, inconstant, transverse fold, the *frenulum labiorum pudendi*, situated just anterior to the posterior commissure of the labia majora. Anterior to the frenulum is the *fossa navicularis* of the vestibule.

The vestibule.—The space between the two labia minora is termed the vestibule, and into its most anterior portion there projects the extremity of an erectile organ, the *clitoris* (fig. 1037), which is comparable to the penis of the male. It is, however, relatively small and is not perforated by the urethra, which lies below it. It is composed of two masses of erectile tissue, the *corpora cavernosa clitoridis*, which differ from the corresponding structures of the penis only in size. They are attached posteriorly to the rami of the pubis by the *crura clitoridis* (fig. 1038), and as they pass forward they converge and meet together to form the body of the organ, which, beneath the symphysis pubis, bends sharply upon itself

Fig. 1038.—Diagrammatic Representation of the Perinæal Structures in the Female.



and passes posteriorly beneath the anterior commissure of the labia majora. Distally the corpora cavernosa abut upon another mass of erectile tissue, which fits like a cap over their extremities; it is formed by an anterior prolongation of the bulbi vestibuli and is termed the *glans clitoridis*, being comparable to the glans penis, from which it differs only in not being perforated by the urethra.

A short distance posterior to the glans clitoridis is the opening of the *urethra* [orificium urethræ externum], situated upon the summit of a slight papilla-like elevation. Lateral to this orifice are sometimes found the openings, one on either side, of two elongated slender ducts, the *paraurethral ducts* (ducts of Skene). Still more posteriorly is the external orifice of the *vagina* [orificium vaginæ], partially closed in the virgin by the *hymen*. Lateral to this, in the angles between the hymen and the labium minus on either side, is the opening of the greater vestibular gland, while the lesser glands open at various points on the floor of the vestibule, sometimes at the bottom of more or less distinct depressions.

Beneath the floor of the vestibule and resting upon the superficial layer of the urogenital trigone are two oval masses of erectile tissue, the *bulbi vestibuli* (fig. 1038), homologous with the corpus cavernosum urethræ of the male. They consist principally of a dense network of anastomosing blood-vessels, enclosed within a thin investment of connective tissue. From the main mass of each bulbus a slender prolongation, the pars intermedia, extends anteriorly past the side of the urethra, to form the glans clitoridis.

The *greater vestibular glands* [gl. vestibularis major (Bartholini)] or glands of Bartholin (fig. 1038) represent the bulbo-urethral glands of the male. They are two small, compound tubular glands, situated one on either side immediately posterior to the bulbi vestibuli.

The single *duct* of each gland opens on the floor of the vestibule in the angle between the hymen and the orifice of the vagina and a little posterior to the mid-transverse line of the latter. Numerous small tubular glands occur in the integument forming the floor of the vestibule; they are termed the *lesser vestibular glands* and are especially developed in the interval between the urethral and vaginal orifices.

The **muscles** of the female external genitalia (fig. 1038) correspond to the perineal muscles of the male (see Section IV). There are two *transverse perineal* muscles, which have the same relations as in the male, and two *ischio-cavernosi,* which are related to the crura clitoridis just as those of the male are to the crura penis. The *bulbo-cavernosi,* however, present somewhat different relations, each being band-like in form, arising from the central point of the perineum and extending forward past the orifice of the vagina, over the greater vestibular gland and the bulbus, to form with its fellow of the other side a tendinous investment of the body of the clitoris. The two muscles act as a sphincter to the vagina and are sometimes termed the *sphincter vaginæ.*

The urethra.—The **urethra** of the female [urethra muliebris] (figs. 1034, 1036) corresponds only to the prostatic and membranous portions of the male and is a relatively short canal, measuring from 3.0 to 4.0 cm. in length. At its origin from the bladder it lies about opposite the middle of the symphysis pubis and thence extends downward and slightly forward to open into the vestibule between the glans clitoridis and the orifice of the vagina. Its posterior wall is closely united with the anterior wall of the vagina, especially in the lower part of its course where it forms the *urethral carina* of the vaginal wall; laterally and anteriorly it is surrounded by the pudendal plexus of veins.

Structure.—Its walls are very distensible, and are lined by a mucous membrane with numerous longitudinal folds, one of which on the posterior side is more prominent and is termed the *crista urethralis.* The mucosa contains numerous small glands [gl. urethrales], a group of which on each side is drained by the inconstant ductus paraurethralis. External to the loose submucosa is a sheet of smooth muscle, whose fibres are arranged in an outer circular and an inner longitudinal layer, a rich plexus of veins lying between the two and giving the entire sheet a somewhat spongy appearance. The circular fibres are especially developed at the vesical end of the canal, forming there a strong sphincter, and striped muscle fibres, derived from the bulbo-cavernosus, form a sphincter around its vestibular orifice. The female urethra differs from that of the male in not being enclosed within a prostate gland; but what are probably rudiments of this structure are to be found in the groups of urethral glands drained by the paraurethral ducts.

Vessels and nerves.—The *arteries* supplying the external female genitalia are the internal and external pudendals, and the *veins* terminate in corresponding trunks. The *lymphatics,* which are very richly developed, drain for the most part to the inguinal nodes; those from the urethra pass to the iliac nodes. The *nerves* are partly sympathetic and partly spinal; the former are derived from the hypogastric plexus, the latter principally from the pudendal, the anterior portions of the labia majora being supplied by the ilio-inguinal and the external spermatic branch of the genito-femoral.

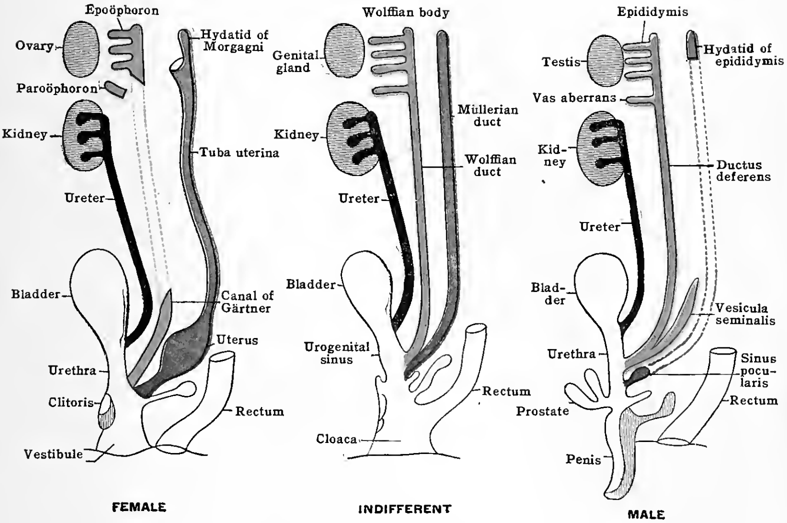
DEVELOPMENT OF THE REPRODUCTIVE ORGANS

It has already been pointed out (p. 1267) that during development a transitory excretory organ, the **mesonephros** or **Wolffian body,** reaches a high degree of development, and its duct, the **Wolffian duct,** opens into a **cloaca** or common outlet for the intestinal and urinary passages. The mesonephros forms a strong projection from the posterior wall of the abdomen into the body cavity, and on the medial surface of the peritoneum which covers it a thickening appears which is termed the **genital ridge.** The upper part of this ridge becomes the ovary or testis, as the case may be, while the remainder of it becomes the ovarian and round ligaments in the female and the gubernaculum testis in the male.

As the ovary or testis develops the tubules of the upper part of the Wolffian body enter into relation with it, forming, indeed, in the case of the testis, a direct union with the seminferous tubules. The Wolffian body then becomes divisible into a reproductive and an excretory portion, and, when the metanephros or permanent kidney develops, the latter portion degenerates, leaving only a few rudiments, such as the paroöphoron in the female (p. 1269) and the vas aberrans and paradidymis (p. 1257) in the male. The reproductive portion also becomes much reduced in the female, persisting as the tubules of the epoöphoron (p. 1269), but in the male it forms the lobules of the epididymis and serves to transmit the spermatozoa to the Wolffian duct.

In addition to the Wolffian duct, a second duct, the **Müllerian,** occurs in connection with the genito-urinary apparatus, and, like the Wolffian duct, it opens below into the cloaca. The history of the two ducts is very different in the two sexes. In the **male** the Wolffian duct persists to form the vas deferens, of which the seminal vesicle is an outgrowth and the ejaculatory duct the continuation, while the Müllerian duct degenerates, its lower end persisting as the prostatic utriculus and its upper end as the appendix of the epididymis. In the **female,** on the contrary, it is the Müllerian duct which persists, its lower portion fusing with the duct of the opposite side to form the vagina and uterus, while its upper portion forms the tuba uterina. Inhibition of the fusion of the lower ends of the two Müllerian ducts gives rise to the bihorned or divided uteri, or the bilocular uteri and vaginæ which occasionally occur. The Wolffian duct in the female almost completely disappears, persisting only as the longitudinal tube of the epoöphoron and as the rudimentary canal of Gärtner (p. 1275). With the degeneration of the mesonephros the peritoneum which covered it becomes a thin fold, having in its free edge the Müllerian duct and, on the fusion of the lower ends of the ducts, the two folds also fuse and so give rise to the broad ligament.

FIG. 1039.—DEVELOPMENT OF THE REPRODUCTIVE ORGANS.



The developmental relations of the male and female organs may be seen from figure 1039 and also from the following table:—

	MALE	FEMALE
Genital ridge	Testis	Ovary
	Gubernaculum testis	Ovarian ligament Round ligament
Wolffian body	Head of epididymis	Epoöphoron
	Paradidymis Vas aberrans	Paroöphoron
Wolffian duct	Body and tail of epididymis	Longitudinal tubule of epoöphoron
	Ductus deferens	Canal of Gärtner
	Ejaculatory duct	
Müllerian duct	Appendix of epididymis (?)	Uterine (Fallopian) tube
		Uterus
	Prostatic utriculus	Vagina

The development of the external organs of generation in the two sexes presents a similar differentiation from a **common** condition. The division of the cloaca to form a **urogenital sinus** and the terminal part of the rectum has already been noted (p. 1253). In the floor of the sinus, to the sides of and above the urethral orifice, erectile tissue develops, forming a **genital tubercle.** An outpouching of that portion of the anterior abdominal wall to which the round ligament of the uterus or the gubernaculum was attached occurs to form the **genital swellings,** lying one on either side of the sinus, and medial to these a pair of folds develop at the borders of the sinus, enclosing the genital tubercle above and forming the **genital folds.**

This condition practically represents the arrangement which persists to adult life in the **female.** The genital tubercle becomes the clitoris, the genital swellings the labia majora, the genital folds the labia minora, and the urogenital sinus, into which the urethra and Müllerian ducts (vagina) open, is the vestibule. In the **male** the development proceeds farther. The genital tubercle elongates to form the penis, and the free edges of the genital folds meet together and fuse, closing in the urogenital sinus and transforming it into the cavernous portion of the urethra, thus bringing it about that the male urethra subserves both reproductive and urinary functions. The genital swellings also meet and fuse together below the root of the penis, forming the scrotum.

The homologies of the parts in the two sexes may be seen from the following table:—

	Male	Female
Urogenital sinus	Cavernous portion of urethra	Vestibule
Genital tubercle	Penis	Clitoris
Genital folds	Integument and prepuce of penis	Prepuce of clitoris and labia minora
Genital swellings	Scrotum	Labia majora

Inhibition of the development of the parts in the male or their over-development in the female will produce a condition resembling superficially the normal condition of the opposite sex, and constituting what is termed *pseudo-hermaproditism;* or a failure of the genital ridges to fuse may result in what is known as *hypospadias,* the cavernous portion of the urethra being merely a groove in the under surface of the otherwise normal penis.

SECTION XII

THE SKIN, MAMMARY GLANDS AND DUCTLESS GLANDS

Rewritten for the Fifth Edition

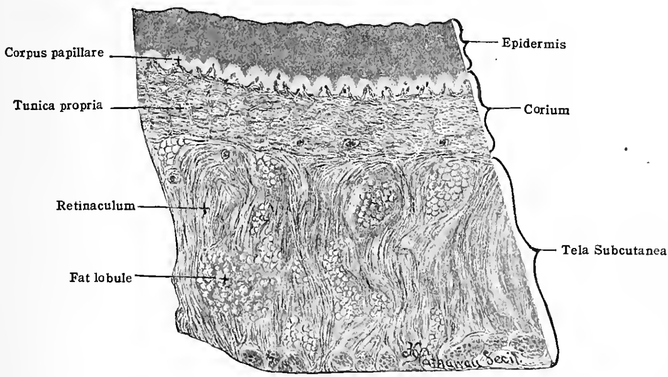
By ABRAM T. KERR, B.S., M.D.

PROFESSOR OF ANATOMY IN THE CORNELL UNIVERSITY MEDICAL COLLEGE

THE SKIN

THE covering which envelops the whole external surface of the body is known as the **common integument** [integumentum commune]. This consists of the **cutis** or skin proper and of *appendages*, the hair, nails, and skin glands. The cutis is composed of a superficial epithelial layer, the **epidermis,** derived from the ectoderm, and a deep connective tissue layer developed from the mesoderm and divided into a superficial part, the **corium,** and a deeper part the **tela subcutanea** (figs. 1040, 1041). The subcutaneous tela is not usually considered as a part of the skin in a restricted sense, but as a superficial fascia, which name is often applied to it.

Fig. 1040.—Magnified Section of the Thickened Skin of the Palm of the Hand. ×6



The skin forms an encasement for the entire body broken only in the regions where it merges with the mucous membranes. It serves not only as a direct physical protection to the underlying structures, but also, through its function as an organ of touch and of general sensibility, it indirectly protects the body by the action of the special end organs and peripheral terminations of the sensory nerves which thus bring the body into relations with its surroundings. Through the radiation and conduction of heat to and from the blood circulating in it, through the amount of secretion of its glands and the evaporation from its surface, the skin forms the principal organ for the regulation of the bodily heat. By means of the action of its sweat and sebaceous glands it possesses an important secretory function. It has also a minor rôle as an organ of respiration and absorption.

The **surface area** of the skin corresponds approximately to the surface of the body and naturally varies with the size of the individual. It has been variously estimated at from 10,500 to 18,700 sq. cm. for a medium-sized adult male.

The **aperturæ cutis** are holes through the skin where it joins with the mucous membrane, usually without sharp line of demarcation, at the nares, the rima oris, the anus, and the external urethra in the male, and at the vaginal vestibule in the female.

Owing to the fact that the skin extends beyond the surface at the aperaturæ cutis, and covers the major and minor pudendal labia, and the prepuce and extends into the external acoustic canal, the surface area is slightly greater than the surface of the body.

The **thickness** of the skin varies in different regions of the body and also in different individuals. The mean thickness is between 1 and 2 mm., the extremes ranging from .3 to 4.0 mm. or more. This is exclusive of the subcutaneous tela. The thickness appears to be in direct proportion to the amount of friction and pressure to which the part is subjected. Thus it is thicker on the dorsal than on the ventral surface of the trunk and neck, and on the flexor than on the extensor surfaces of the hands and feet. Otherwise it is thicker upon the extensor than on the flexor surface of the extremities.

Fig. 1041.—Vertical Section from the Sole of the Foot of an Adult. ×25. (Lewis and Stöhr.)

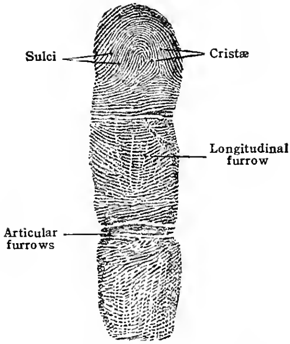
The thickness of the skin is least upon the tympanum and it is also thin upon the eyelids and penis. It obtains a thickness of 3 mm. on the volar surface of hands and plantar surface of the feet and gains a thickness of about 4 mm. on the cephalic part of the back and dorsal surface of the neck. It is thinner in the aged than in the adult, thicker in men than in women, and in the same sex is subject to much individual variation depending upon exercise, occupation, etc. The vascularity of the skin also influences its thickness.

Over most of the surface of the body the skin is **elastic** and so loosely attached that it may be stretched to a greater or less extent. The elasticity varies in different individuals. Closely associated with the elasticity is the manner of **attachment** of the skin to underlying structures. This varies somewhat according to the tissues which are covered but the great motility is due in the main to the very oblique arrangement of the connective tissue and elastic fibres of the deeper layers of the skin; the fixity to the more vertical arrangement of these fibres. An understanding of the looseness and elasticity of the skin is of much practical importance to the surgeon in certain operations.

When the traction is slow as over a slow-growing tumour, or over the abdomen and breasts in pregnancy, the skin may be stretched to a very considerable degree. In these cases there are often produced short parallel reddish streaks which when the stretching is relieved are replaced by whitish, silvery lines, **striæ** or **lineæ albicantes,** due to atrophy of the tissues. In spite of this the skin usually retains enough elasticity to contract gradually to its former extent as it does immediately after moderate stretching.

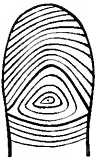
In most parts of the body the attachment is loose so that the skin is movable and may be pinched up into folds. In some places the attachment of the skin is firm and there is no slipping of the skin over underlying parts, as on the glans penis. In some other parts the motion is very limited as in the scalp and the volar surface of the hands and the plantar surface of the feet.

Fig. 1042.—Finger Print (Natural Size) Showing Cristæ and Sulci.



The **colour** of the skin varies greatly. It may be white, yellow, black, red, or any of the shades of these colours, and, according to the colour, the races of mankind have been roughly divided. The colouration is due partly to pigment and partly to the blood within the cutaneous vessels. The amount of pigment varies with race, age, sex, and with exposure to the sun and air. In the white races the skin of the child is a pinkish white, tending to become dead white in the adult and yellowish in the aged, and it is normally more pigmented in certain regions, such as the axillary region, the scrotum, the vulva, and the mammary areola.

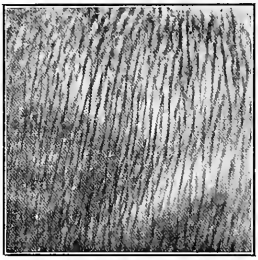
Fig. 1043.—Diagram Showing the Arrangement of the Principal Cristæ of the Thumb



The colour of the white, yellow, red, and black races is not produced by the climate, as we find different races existing under the same climatic conditions and the same coloured race under different conditions of climate. Each race presents several variations of colour; for example, in the white race we distinguish a blonde, a brunette, and an intermediate type. Anthropologists distinguish twenty to thirty different shades of colour in the skin. In blondes of the white race under the action of strong sun light the skin passes from a rose white to a brick red or becomes pigmented in spots, **freckles.** In the first case the pigment in the skin is not increased to any great extent but the skin is affected by a superficial inflammation, **erythema,** associated with exfoliation and often with the formation of blisters. In brunettes of the white race the sun burns the skin a dark yellowish or reddish brown, the degree of pigmentation here being increased and is spoken of as **tan.** The colouration is only temporary and diminishes on withdrawal from exposure. The sun darkens the skin in the yellow races also. In the newborn of the black races the skin is of a reddish colour, since the pigment although developed to some extent is at birth obscured by overlying opaque cells which later become transparent. The newborn of the yellow races are also lighter than their parents. In white races the shade of the skin is clearer on the ventral surface of the trunk and on the flexor surface of the extremities. In the black races the volar surface of the hands and the plantar surface of the feet as well as the sides of the digits are less deeply pigmented than the rest of the body. The colour of the skin is greatly influenced by the blood in its deeper layers which during life gives it a more or less distinctly reddish tinge, varying directly with the vascularity and inversely with the thickness of the epidermis. Absence of the normal pigment is a not uncommon congenital anomaly producing albinism or leukoderma. It may affect all the skin structures or it may be partial.

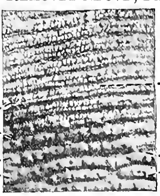
The skin presents certain **elevations** and **depressions** due to the fact that it follows more or less closely the contour of the underlying structures, but in addition to this it possesses certain elevations and depressions peculiarly its own. They are found on the skin in various parts of the body. Some are permanent, others only temporary. Large permanent **folds** which include all the layers of the skin are seen, as the prepuce of the penis and the pudendal labia. The most marked depression is the **umbilical fovea.** Other conspicuous folds and furrows are seen in the neighbourhood of the lips and eyelids. Certain other less permanent folds and furrows are produced by the action of the joints, **joint-furrows,** and of the muscles of expression of the skin, **"wrinkles."**

Fig. 1044.—From a Photograph of the Superficial Furrows on the Back of the Hand. (× 1.)



Other minute folds and furrows which affect only the epidermis and the superficial layer of the corium are seen in various places. These are represented by the numerous fine superficial creases, unassociated with elevations, forming rhomboidal and triangular figures over almost the whole of the surface of the skin (figs. 1042, 1043). They are especially numerous on the dorsal surface of the hands (fig. 1044). The fine curvilinear ridges [cristæ cutis] with intervening furrows [sulci cutis] arranged in parallel lines in groups on the flexor surface of the hands and feet are also of this type. They form patterns characteristic for each individual and permanent throughout life.

Fig. 1045.—From a Photograph of the Skin Ridges and Papillæ of the Palm of the Hand. Epithelium Completely Removed Above; Partly Removed Below. (× 5.)



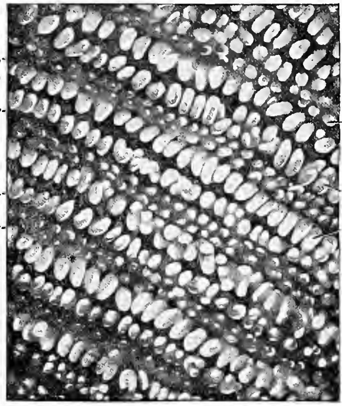
Among the projections are the large permanent folds of skin such as the **labia pudendi,** the **preputium penis,** the **frenula preputii, clitoridis,** and **labiorum pudendi,** and less marked ridges as the median **raphe** of the perineum, scrotum and penis, and the **tuberculum labii superioris.** Of a somewhat different sort are the **touch pads** [toruli tactiles] of the hands and feet. Among the larger depressions in addition to the **umbilical fovea,** is the **coccygeal foveola,** and a considerable number of well-marked permanent furrows found in various places, such as the **nasolabial** and **mentolabial sulci,** the **philtrum labii superioris,** the **infraorbital sulcus,** and the **infra-** and **supraorbitial palpebral sulci.** There are numerous **articular furrows** on both the flexor and extensor surfaces produced by the action of the joints, and associated with intervening folds of skin, particularly on the dorsal surface. They are especially noticeable on the hands. Variations of the palmar joint sulci are due to variations in opposition of the thumb and the use of the fingers and the relative arrangement of the thumb and fingers and joints. They are of especial medical and surgical importance as indicating topographically the position of the joints, their relation to which has been recently made clearer by means of the X-ray.

The folds and furrows brought about through the action of the skin muscles run at right angles to the muscle fibres and are more or less transitory at first but become more permanent through repeated or long-continued action. They are represented by the **wrinkles** of the forehead, the lines of expression of the face, the transverse wrinkles of the scrotum and the radiating folds around the anus. The more superficial **cristæ cutis** and **sulci cutis** are arranged in groups within and around the touch pads, on the volar surface of the hands and the plantar surface of the feet (figs. 1042, 1043). The cristæ of each group are parallel. They correspond to the rows of papillæ of the corium.

Because the patterns of the cristæ and sulci are characteristic for the individual, and permanent from youth to old age, they have been classified in a number of types and are important medicolegally as a means of identification. The various systems of classification are based upon the arrangement over the distal phalanges of the fingers and make use of (1) a transverse ridge which is parallel with the articular plicæ (2) a curved ridge with its convexity distally and more or less closely meeting the first, medially and laterally, and (3) the curved and concentric ridges between these two (fig. 1043).

There are also a great number of minute depressions which mark the points where the hairs pierce the surface and where the glands open. These are popularly known as **pores**. Under

FIG. 1046.—PAPILLÆ OF THE CORIUM AFTER MACERATION. FROM RETOUCHED PHOTOGRAPH. EPITHELIUM REMOVED BY MACERATION. (× 25.)



the influence of cold and emotion the hair muscles contract and cause a slight elevation of the skin at the point where the hair emerges. This roughened appearance of the skin is popularly known as "goose-flesh."

A complex wrinkling of the skin appears in old age, or in the course of exhausting diseases, as a result of loss of elasticity and from absorption of the cutaneous and subcutaneous fat. Rounded depressions called **dimples** are produced by the attachment of muscle-fibres to the deep surface of the skin, as on the chin and cheek, and are made more evident by the contraction of these fibres. Others are produced by the attachment of the skin by fibrous bands to bony eminences, as the elbow, shoulder, vertebræ, and posterior iliac spines. They are best seen when the subcutaneous adipose tissue is well developed.

The **cutis** is made up of two layers which are structurally and developmentally markedly different. The superficial ectodermic portion, **epidermis,** is made up almost entirely of closely packed epithelial cells, the deeper mesodermic part, **corium,** is formed largely of connective-tissue fibres.

The **epidermis** (cuticle, scarf-skin) is a cellular non-vascular membrane which forms the whole of the superficial layer of the skin and at the great openings through the skin, as the mouth and anus, blends gradually with the mucous membrane. It represents from one-tenth to over half the thickness of the skin, in different parts of the body, the usual thickness being .05 to .2 mm., ranging from .03 mm. to nearly 3 mm. The thickness varies also in different individuals. Its deep surface is molded exactly to the underlying corium but its superficial surface fails to reproduce all of the irregularities of the latter. In spite of this close association, blood-vessels never enter the epidermis.

Structure of the epidermis.—The cells of the epidermis are packed together in many irregular layers. The deepest cells are soft protoplasmic, somewhat elongated, perpendicular to the surface of the corium and joined together by fine fibrils; more superficially they become round or polyhedral. These cells together with several more superficial layers form a stratum from which the other cells of the epidermis are developed and which therefore are known as the **stratum germinativum** (Malpighii). The cells in the superficial part of this stratum, in some situations, have a granular appearance forming a layer which is called the **stratum granulosum.** Superficial to this there is, also only in some places, a layer in which the cells are somewhat indistinct and transparent, and therefore known as the **stratum lucidum.** This is a transition between the softer and more opaque stratum germinativum and the firmer and more transparent superficial layer formed of large, flattened, dry, horny cells, known as **stratum corneum.**

In general the stratum germinativum is thicker than the stratum corneum. In certain parts as the face, the back, the back of the hands and feet, the two layers are equal in thickness. In other regions, as in the volar surface of the hands and plantar surface of the feet, the stratum corneum is much thicker than the stratum germinativum varying from two to three or even five times as thick. This increased thickness of the stratum corneum is not due to pressure alone as it is well marked in the fœtus, but it is not improbable that pressure may stimulate the further growth of the cells.

Where the papillæ of the corium are arranged in rows as on the volar surface of the hands and the plantar surface of the feet, the epidermis is molded to these so as to appear as ridges on the surface, already described as cristæ. In most other places the irregularities of the papillæ of the corium do not show on the surface. At short and regular intervals on the cristæ are notches and transverse furrows which mark the openings of the sweat glands.

The separation of the epidermis from the corium by the accumulation of serous fluid between the layers is known as a blister. Sometimes it is only the separation of the superficial layers from the deeper layers of the epidermis.

The skin is regenerated after a blister or a wound by growth of the cells of the stratum germinativum. It is probable that cells of the superficial layers take no part in this. Therefore in skin grafting the surgeon in order to transplant the cells of the stratum germinativum usually includes all the layers of the epidermis and the extreme tips of the papillæ of the corium as shown by the minute bleeding points left on the surface from which the graft has been cut.

The **pigment** which gives the main colour to the skin is caused by the accumulation of pigment granules, melanin, in the deepest cells of the stratum germinativum. It does not occur until after the sixth month of fœtal life and develops chiefly after birth. The blackness of the skin of the negro depends almost entirely upon this pigment. Pigment granules are also found to a less extent in more superficial cells and sometimes in the corium.

Development of the epidermis.—The epidermis is derived from the ectoderm, in early embryos appearing as a double stratum of cells, the superficial layer of which is known as the epitrichium or periderm, the deep layer becomes the stratum germinativum. By multiplication of the deep cells a number of layers are produced and the more superficial cells tend to assume the adult characteristics. At about the sixth month of fœtal life the epitrichial layer finally disappears. The surface layers are cast off and mixing with the secretion of the cutaneous glands form a yellowish layer over the surface of the skin of the fœtus, the *vernix caseosa.*

Growth continues throughout life. New cells are formed in the deeper layers pushing the older cells toward the surface. The character of the cells changes as they approach the surface, the change being quite abrupt at the level of the stratum lucidum. As the form of the cells changes, chemical and physical alterations of their contents occur. In most places the superficial cells are represented by thin scales but in the palms and soles the cells are somewhat swollen. The superficial cells are being constantly thrown off and replaced by deeper ones.

The **corium** (cutis, cutis vera, derma) is a fibrous vascular sheath composed of interwoven bundles of connective-tissue fibres intermixed with elastic fibres, connective-tissue cells, fat, and scattered unstriped muscle-fibres. It is traversed by rich plexuses of blood-vessels, lymph-vessels, and nerves, and encloses hair-bulbs and sebaceous and sudoriferous glands. It varies in thickness from .3 mm. to 3.0 mm. or more, usually ranging from .5 to 1.5 mm. It is to this layer that the strength and elasticity of the skin are due and it is also only this layer which when properly cured we know as leather.

The superficial layer of the corium is of finer, closer texture, free from fat, and forms a multitude of eminences called **papillæ corii** (figs. 1040, 1045, 1046) which project into corresponding depressions on the deep surface of the epidermis. For this reason this part of the corium although but indistinctly separated from the deeper layer is called the **corpus papillare.**

Some of the papillæ contain vessels, others nerves, hence they are known as vascular or tactile papillæ. They are very closely set, varying considerably in number in different parts of the body from 36 to 130 to a square millimetre, and it has been estimated that there are about 150 million papillæ on the whole surface. They also vary greatly in size not only in different regions but in the same region, being from .03 to .2 mm. or more in height.

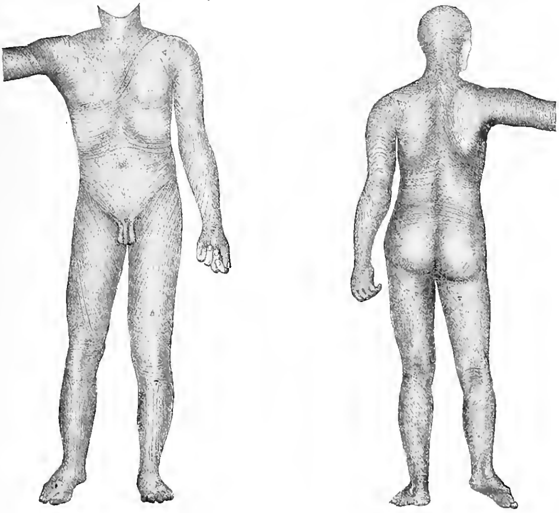
The deeper layer of the corium, the **tunica propria** (stratum reticulare), is composed of coarser and less compact bands of fibrous tissue intermingled with small fat lobules. The fibrous and elastic tissue is arranged for the most part in intercrossing bundles nearly parallel to the surface of the skin.

The bundles running in some directions are usually more strongly developed and more numerous than those in others but the direction of the strongly developed bundles varies in different parts of the body. In general those are best developed which have a direction parallel with the usual lines of tension of the skin, hence it results that wounds of the skin tend to gape most at right angles to these lines. The bundles take a direction nearly at right angles to the long axis of the limbs, and on the trunk run obliquely, caudally, and laterally from the spine (figs. 1047, 1048). On the scalp, forehead, chin, and epigastrium, equally strong bundles cross in all directions, and a round wound, instead of being linear as elsewhere, appears as a ragged or triangular hole. The arrangement of the connective-tissue bundles influences the arrangement of the blood-vessels of the skin.

The **tela subcutanea** or superficial fascia is also a fibrous vascular layer which passes as a gradual transition without definite line of demarcation from the deep surface of the tunica propria of the corium to connect it with the underlying structures.

Like the tunica propria it is composed of bundles of connective tissue containing elastic fibres and fat, but the bundles are larger and more loosely arranged, and form more distinct connective-tissue septa, which divide the fat, when present, into smaller and larger lobules. Where these connecting strands are especially large and well defined, they are known as **retinacula.** Over almost the whole surface of the body the connective-tissue strands of the tela

Figs. 1047 and 1048.—Diagrams Showing the Arrangement of the Connective Tissue Bundles of the Skin on the Anterior and Posterior Surfaces of the Body. (After Langer.)



are arranged nearly parallel with the surface, and bind the skin so loosely to the parts beneath that it may stretch and move freely over the deeper parts. In some situations the connective-tissue bundles of the tela subcutanea run almost at right angles to the surface and bind the skin firmly to the deep fascia, as in the flexor surface of the hands and feet and in the scalp and face.

The quantity of subcutaneous fat varies considerably in different parts of the body. It is, for instance, entirely absent in the penis, scrotum, and eyelids. When it is abundant, the subcutaneous layer is known as the *panniculus adiposus.*

In some situations, as in the caudal portion of the abdomen and in the perineum, the connective tissue is so arranged that the panniculus may be divided into layers, so that a superficial and a deep layer of the superficial fascia may be recognised. The fat is well developed over the nates, volar surface of the hands and plantar surface of the feet, where it serves as pads or cushions; in the scalp it appears as a single uniform lobulated layer between the corium and the aponeurosis of the epicranial muscle; and on other parts of the surface it is somewhat unequally distributed and shows a tendency to accumulate in apparent disproportion in some localities, as on the abdomen, over the symphysis pubis, about the mammæ in females, etc. Everywhere except on the scalp it may undergo rapid and visible increase or decrease under the influence of change of nutrition.

The amount of *elastic tissue* mixed with the white fibrous connective tissue of which the corium and subcutaneous tela mainly consist varies in the different parts of the body. It is especially abundant in the deeper layer of the tela over the caudal part of the ventral abdominal wall where it forms almost a continuous sheet. Many elastic fibres also accompany the blood-vessels and are mingled with the connective-tissue sheaths around the hairs, the sweat glands, and their ducts.

The *papillæ corii* are usually simple cones but some are bulbous at their ends and others have duplicated apices. They may be perpendicular to the surface or oblique, in some places overlapping. Those on the flexor surfaces of the hands and feet are best developed and are arranged in rows so as to form long parallel curvilinear ridges, two of which are grouped together and correspond to one crista on the surface of the epidermis (figs. 1045, 1046). When there are no papillary ridges the papillæ are irregularly scattered, shorter, and may disappear in places or be replaced by ridges. The papillæ serve to give a greater surface area to the corium so as to bring a greater number of blood-vessels and nerves into closer relation with the epidermis and thus with the surface of the body. They are best developed where the epidermis is thickest. Thus they are the largest on the flexor surface of the hands and feet and beneath the nails and are smallest on the face, scrotum, and mammæ.

The skin, as removed in the dissecting room, usually includes the epidermis and more or less of the corium and subcutaneous tela. The cut surface is formed of connective tissue which has a shining bluish-white appearance with minute pits closely scattered over the surface. These pits are usually more or less completely filled with small yellow fat lobules.

Skin muscles.—In the subcutaneous tela and the corium muscle fibres are found in large and small groups. These are of two kinds, striated muscle and unstriated muscle.

Subcutaneous planes of *striated muscle* are relatively scanty in man when compared with the great panniculus carnosus of the lower mammalia. This is mainly represented by the platysma in the neck which has both its origin and part of its insertion in the skin. Closely associated with this are the muscles of expression of the face and the palmaris brevis muscle which have one end terminating in the deep surface of the skin. The epicranial muscle is also considered by some to belong to this group.

Unstriated muscle fibres are scattered through the corium collected into bundles in the neighbourhood of the sebaceous glands and the hairs. They are described in connection with these latter (p. 1293). In addition to these unstriated muscles are found in the scrotum as the dartos, in the perineum, around the anus, and beneath the papilla and areola of the mammary gland.

Bursæ mucosæ subcutanea.—In some situations where the integument is exposed to repeated friction over subjacent bones or other hard structures its movements are facilitated by the development of sac-like interspaces in the subcutaneous tissue, the **subcutaneous mucous bursæ.** They are similar to the more deeply placed bursæ which are found in relation with muscle tendons. Their occurrence is quite variable. In some individuals they are numerous, in others very few. They have a considerable practical importance from the fact that they may become greatly swollen.

The most constant subcutaneous mucous bursæ are the following:

Bursa anguli mandibulæ; B. subcutanea prementalis, between the periosteum and soft parts over the tip of the chin; **B. subcutanea prominentiæ laryngeæ** over the ventral prominence of the thyreoid cartilage of the larynx (often found in the male; **B. subcutanea acromialis,** between the acromion and the skin; **B. subcutanea olecrani,** beneath the skin on the dorsal surface of the olecranon; **B. subcutanea epicondyli humeri lateralis,** found beneath the skin over the lateral epicondyle of the humerus (occasional); **B. subcutanea epicondyli humeri medialis,** between the skin and the medial epicondyle of the humerus (more frequent); **B. subcutanea metacarpophalangea dorsalis,** between the skin and the dorsal side of the metacarpophalangeal joints (occasional, especially the fifth); **B. subcutanea digitorum dorsalis,** beneath the skin over the proximal finger-joints; and rarely over the distal finger-joints; **B. subcutanea trochanterica,** between the skin and the great trochanter of the femur; **B. subcutanea præpatellaris,** beneath the skin covering the caudal half of the patella; **B. subcutanea infrapatellaris,** between the skin and the cephalic end of the ligamentum patellæ; **B. subcutanea tuberositatis tibiæ** ventral to the tibial tuberosity, covered by skin or by skin and crural fascia; **B. subcutanea malleoli lateralis,** between the skin and the point of the lateral malleolus; **B. subcutanea malleoli medialis,** between the skin and medial malleolus; **B. subcutanea calcanea,** in the sole of the foot between the skin and the plantar surface of the calcaneum; **B. subcutanea sacralis,** beneath the skin which covers the lumbodorsal fascia and the region between the sacrum and coccyx.

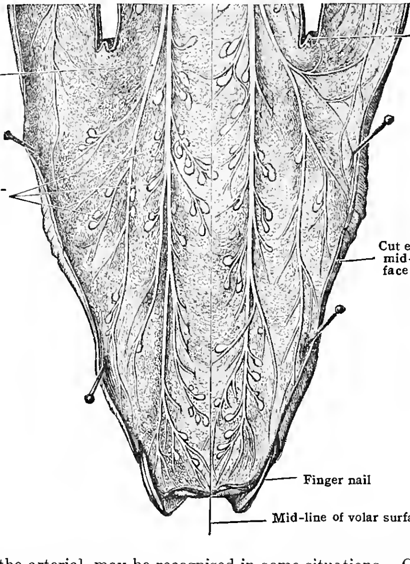
Blood-vessels of the skin.—Both the corium and the subcutaneous tela are very vascular, but the size and number of vessels varies in different situations. Although the origin of the cutaneous arteries from the deep arteries and the positions where the subcutaneous arteries pierce the muscles vary greatly, the areas supplied by certain groups of arteries and the direction in which the arteries of the skin run show much regularity. Moreover the metameric arrangement of the arteries in the skin is clearly seen, especially upon the trunk. We can recognise two groups of skin arteries. One group is represented by a small number of rather large branches which are distributed throughout or principally in the subcutaneous tela and corium, as the inferior superficial epigastric artery, the arteries of the scalp, etc. These arteries tend to disturb the metameric arrangement. In the other group the arteries are intrinsically for the supply of other organs but give off small end twigs to the skin, e. g., the arteries to the superficial muscles.

The arteries enter the corium from the subcutaneous tela, break up into smaller branches anastomose freely and in the deepest layer of the corium form a network, the **cutaneous rete** (subcutaneous plexus), **rete arteriosum cutaneum,** from which small branches are given off to supply the fat and sweat glands and also to the papillary layer of the corium. Here another network of arteries is formed, the **subpapillary rete, rete arteriosum subpapillare.** From the subpapillary plexus, minute twigs pass to the papillæ, to the hair follicles, and to the sebaceous and sudoriferous glands.

The **cutaneous veins** like the arteries may be divided into three groups: (1) small radicals which accompany the corresponding arteries and go to make up veins whose main function is to collect the blood from the muscles; (2) larger branches accompanying the arteries whose main course is in the subcutaneous tela as the inferior superficial epigastric vein; (3) large veins which run in the subcutaneous tela but have a course independent of the arteries such as those seen through the skin on the hands and arms. These large vessels will be found described in connection with the general description of the veins (Section V).

Minute venules arise from the capillaries of the papillæ, accompany the arteries and form parallel with the surface of the skin a series of closely connected plexuses. Four such plexuses,

FIG. 1049.—CUTANEOUS NERVES OF THE MIDDLE FINGER AND LAMELLOUS (PACINIAN) CORPUSCLES. (From Toldt's Atlas.)



more distinct than the arterial, may be recognised in some situations. Of these **retia venosa** one is situated just beneath the papillæ, and another at the junction of the corium and subcutaneous tela. They receive branches from the fat, hair follicles, and glands, and empty into the large veins of the skin situated in the subcutaneous tissue.

Lymphatics of the skin.—The cutaneous lymphatic vessels are found in the skin of all parts of the body but are more abundant in certain places. The lymph-vessels of the skin are developmentally among the first lymph-vessels to appear. The larger vessels and glands of the subcutaneous tela will be found described in connection with the general lymphatic system Section VI). In the corium the lymphatics from the papillæ form a **subpapillary network** which opens into a **subcutaneous plexus** connected with the larger lymph-vessels of the subcutaneous tela. There are no lymph-vessels in the epidermis, but this is supposed to be nourished by the lymph in the tissue spaces between the cells and these spaces connect indirectly with the lymph-vessels.

The nerves.—The skin has one of the richest nerve supplies of the body. The nerves are in greater proportion in those parts which are most sensitive. The various skin areas are supplied by specific (segmental) nerves with much greater regularity than in the case of the arteries. The nerves supplying adjoining areas overlap so that there is an intermediate space supplied by both. The variations consist in an extension of one area and a corresponding contraction of an adjoining area. The distribution of the nerves in the skin shows, especially on the trunk and neck, a marked metameric arrangement. The arrangement of these nerves in the subcutaneous tela and their areas of distribution will be found described in detail in the section on the Nervous System.

With the exception of the nerves to the sudoriferous and sebaceous glands, the skin-muscles and blood-vessels, all the cutaneous nerves are sensory. They have diverse modes of termination. Some end in the subcutaneous tela; others, the greater number, terminate in the corium; still others extend to the epidermis.

Toward their termination the nerves branch and rebranch, and just beneath the surface they form a great number of small twigs from which the terminal fibres arise. These may be divided into two groups, those that end freely and those whose termination is surrounded by a capsule. The free ends are slightly enlarged and terminate in the epidermis and in certain regions in the corium. The encapsulated terminations form special end organs and are found in the corium as the **bulbous corpuscles** (end-bulbs of Krause) [corpuscula bulboidea, Krauserii]; the **tactile corpuscles** (corpuscles of Meissner or Wagner) [corpuscula tactus, Meissneri]; and the **genital corpuscles** [corpuscula nervorum genitalia]. In the subcutaneous tela the end-bulbs are seen as the **lamellous corpuscles** (corpuscles of Vater: Pacinian corpuscles), [corpuscula lamellosa; Vateri, Pacini] shown in fig. 1049; the **Golgi-Mazzoni corpuscles** and the **Ruffini corpuscles.** All the terminations except the lamellous corpuscles are microscopic, not exceeding 0.2 mm. in length. The lamellous corpuscles, which are readily seen in reflecting the skin from the fingers and toes, may be as much as 2 mm. long and half as thick (fig. 1049). The exact function of each of the various endings is not known. They are undoubtedly sensory fibres except those to the glands, muscles, and blood-vessels.

Development of the corium and subcutaneous tela.—The corium is developed from the superficial part of the myotome or dermo-muscular plate of mesoderm. At first it is very largely cellular but later fibres are produced. In the earlier stages the corium and tela subcutanea are not distinguishable and only in the later embryonic period may the corium be separated into the papillary stratum and the tunica propria.

THE APPENDAGES OF THE SKIN

The appendages of the skin include: (A) the hairs; (B) the nails; (C) the cutaneous glands; and (D) the mammary glands.

A. THE HAIRS

The **hairs** [pili] are less developed in man than in any other primate. Where well developed they in themselves serve as a protective organ and moreover through their connection with the nervous system they become in a measure organs of special sense. They are strong, flexible, somewhat elastic, and poor conductors of heat. They cover the entire surface of the body with the following exceptions: The flexor surfaces of the hands and feet; the dorsal bends and sides of the fingers and toes; the dorsal surfaces of the distal phalanges of the fingers and toes; the red borders of the lips; the glands and inner surface of the prepuce of the penis and clitoris; the inner surface of the labia majora; the labia minora and the papilla mammæ.

The **size** and **length** of hairs varies greatly not only in different parts of the body but also in different individuals and races. In certain situations the hairs are especially long and large and are designated by special names.

Thus upon the scalp, **capilli,** in the axillary region, **hirci,** and after puberty upon the face in the male, the beard, **barba,** and in the pubic region in both sexes, **pubes.** The pubic hairs extend upon the external genital organs and upon the ventral abdominal wall toward the umbilicus. All of the hairs of these regions are not long and large but short and finer hairs are mixed with them in varying numbers. Strong, well-developed short hairs are found in connection with the organs of sense forming the eyebrows, **supercilia,** the eyelashes, **cilia,** at the entrance to the external acoustic meatus, **tragi,** and at the nares, **vibrissæ.** Upon the extensor surfaces of the extremities, upon the chest, and in other situations in some individuals, especially in adult males, the hairs are also longer and stronger than upon the rest of the body, where they are, as a rule, short, fine and downy. The first hairs appearing in the fœtus are very fine, and are called **lanugo.** The long hairs of the adult scalp may attain a length of 150 cm. or more; the short hairs average from .5 to 1.3 cm. in length, while the lanugo does not exceed 1.4 cm.

Excess of long hairs, **hypertrichosis,** may involve the whole hairy surface of the body. It is usually inherited and affects several individuals in the same family. Local areas of long hairs also occur as over nævi and upon the sacrum. Local congestion due to inflammation, irritation, or pressure may cause hypertrichosis. In women, hair upon the upper lip or other parts of the face may be an inherited peculiarity or due to some abnormality of the sexual organs. It is also not uncommon after the menopause.

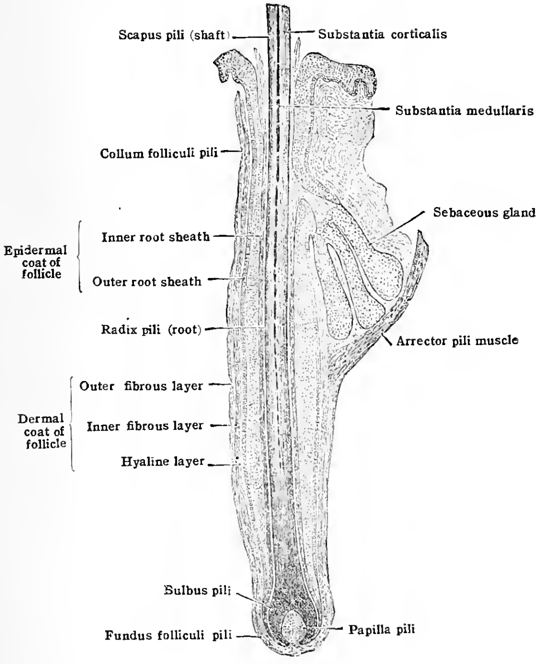
In **diameter** the hairs vary from .005 mm. for the finest lanugo to .203 mm. for the coarsest hair of the beard; but they usually taper toward the tip and also are narrower toward the base. As a general rule, blonde hairs are the finest and black hairs the coarsest.

In **colour** the hairs may be either blonde, brown, black, red, or some gradation of these colours. The colour varies with the race, and also with the individual, and according to age. It is due to pigment in the cells of the hair but is also influenced by the amount of air between the cells.

Greying and whitening of the hair is due not only to a decrease of pigment but also to an increase in the amount of air between the cells. Sudden blanching of the hair is thought to be due almost entirely to an increase in the quantity of this contained air. Whitening of the hair is physiological in old age and not infrequent in younger persons. This may be an inherited peculiarity or may follow mental overwork, nervous shock, or prolonged disease. Local blanching is also seen as the result of disease.

The hair may be straight, waved, curled, or frizzled in varying degree. Here also there is not only an individual but also a racial variation, as instanced in the curled or crinkled hair of the African negro and the straight hair of the American Indian. The curliness is caused by the form and the manner of implantation in the skin. Straight hairs are round or oval in transection

Fig. 1050.—Longitudinal Section of a Growing Hair of the Head. (×30.) (From Toldt's Atlas.)



and curled hairs are more flattened. The root of curled hair has been observed in certain instances, as in the negro, to have a curved course in the skin which may account in a measure for its curliness.

The hairs are *arranged* singly or in groups of from two to five and, except those of the eyelashes, are implanted at oblique angles to the surface of the skin. The directions in which the hairs point are constant throughout life for the same individual. They are arranged in tracts in which the hairs diverge from a centre in whorls, the **vortices pilorum.**

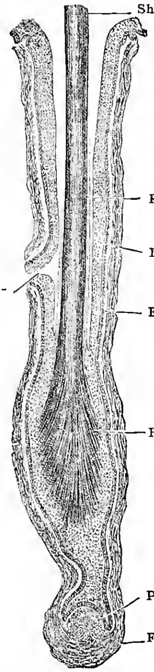
These vortices are found constantly in certain definite regions and apportion the whole hairy surface. The centres of vortices are found at the vertex (sometimes double) upon the face, around the external auditory meatus, in the axilla, in the inguinal region, and sometimes on the lateral surface of the body. These are all paired except as a rule the first. Where adjoining vortices come together the hairs are arranged in lines along which they all point in nearly the same direction, only slightly diverging, forming the **hair streams, flumina pilorum.** In other lines and places the hairs point in converging directions such as at the umbilicus and over the tip of the coccyx.

The number of hairs to the square centimetre varies in different parts of the body and also in the same situation with the individual and with differences in race, colour and diameters.

The hairs are most numerous on the head, ranging from 170 to 300 to the square centimetre at the vertex. They are less numerous on other parts of the body, varying from 23 to 44 (per square centimetre) on the chin, and from 24 to 80 on the forearm. The greatest number is found with blonde hair, the next with brown, then black, and the least with red hair.

The structure of the hair.—Each hair consists of a **shaft** [scapus pili] (fig. 1050) projecting from the free surface of the skin to end (unless broken or cut) in a conical end [apex pili], and of a **root** [radix pili], imbedded in the case of the lanugo hair in the corium and of the larger hairs at various depths in the subcutaneous tela. Surrounding the root is a downgrowth of the skin known as the *follicle* [folliculus pili].

FIG. 1051.—LONGITUDINAL SECTION OF A HAIR READY TO FALL OUT, WITH FOLLICLE FOR NEW HAIR. (×30) (From Toldt's Atlas.)



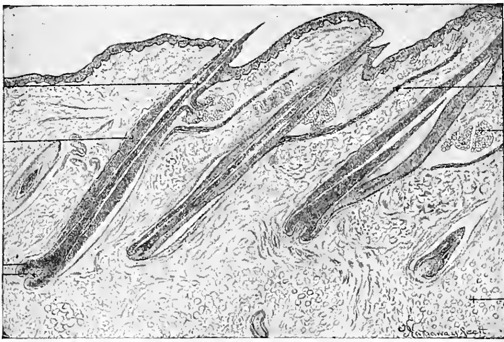
The root of the hair at its deepest parts swells to from one and one-half to three times the diameter of the shaft forming thus the **bulb** [bulbus pili] (fig. 1050). The bulb is hollow and a vascular connective-tissue process, the hair **papilla** [papilla pili] (figs. 1050, 1051) extends from the deepest part of the follicle into the cavity in its base. The follicle consists of an external connective-tissue portion formed by the corium, the **theca folliculi** and an internal epithelial portion belonging to the epidermis and divided into two portions, the **inner** and **outer root sheaths** (fig. 1050).

The theca of the follicle is composed of an outer loose longitudinal and a middle circular layer of connective tissue and an inner basement membrane. The outer root sheath is directly connected with the stratum germinativum of the epidermis. In its deeper part it consists of several layers of cells but of only one near the surface. The inner root sheath has been divided into three layers. At the junction of the outer and middle thirds of the follicle of most of the hairs, the ducts of usually two or more sebaceous glands connect with the space between the hair and its follicle (figs. 1050, 1051). Immediately beneath this is the narrowest part of the follicle the **neck** [collum folliculi pili], especially important as the position of the nerve ending of the hair.

The **hair** is formed of epithelial cells arranged in two and sometimes three layers; an outer single-celled layer of transparent over-lapping cells, the **cuticle**, an intermediate layer several cells thick formed of irregular fusiform horny cells containing pigment and arranged in fibrous strands, the **substantia corticalis**, and in some of the larger hairs an internal two or three celled layer of angular cells occupying the center of the hair shaft for only part of its length, the **substantia medullaris**. Between both the cortical and medullary cells are spaces containing air. In the hair bulb, where the cells are larger and softer the layers are not distinguishable. The cells here being in process of division and being gradually transformed into the horny cells of the shaft.

Many of the hairs have in connection with their follicle round or flat bundles of unstriped muscle fibres, the **arrectores pilorum** (figs. 1050, 1052). These are situated on the side toward which the hairs point, their deep ends being attached to the hair follicle beneath the sebaceous glands which they more or less embrace and their superficial ends connected with the papillary layer of the skin. Contraction of the arrectores not only causes the hairs to become more erect and the skin around them to project somewhat causing "goose flesh," but also compresses the sebaceous glands which are situated between the follicle and muscle and helps to empty the glands of their secretion.

FIG. 1052.—VERTICAL SECTION OF THE SKIN FROM SCALP. (× 20.)



The blood supply of the hairs.—The hair follicles are surrounded by a capillary network of arteries connected with those of the corium and the papillæ are also supplied with loops of arteries.

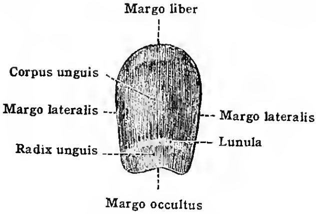
The **nerves** of the corium supply branches to the hairs. Some of these branches enter the papillæ, others surround the follicle at its neck and are distributed among the cells of the outer root sheath.

Development.—The hairs are developed from the epidermis by thickenings and downgrowths into the corium of plugs of epithelium. The deepest parts of these plugs become swollen to form bulbs and from these the hairs are produced. The central cells of the epithelial downgrowths disintegrate producing the lumen of the follicle. The hairs continue to grow from the deeper cells and protrude from their follicles between the fifth and seventh fœtal months. Abnormally they may be scanty at birth and rarely entirely absent, **alopecia**. The lanugo hairs which cover all the hairy parts of the body at birth are soon shed and replaced by new hairs in the old follicles. Throughout life also the hairs are being constantly shed and replaced by new ones. This is accompanied by cornification of the bulb and fibrillation of the deep end of the hair (fig. 1051). Thinning of the hair and baldness occur when the shed hairs cease to be replaced. This is common in old age and a premature baldness appears to run in certain families. The rate of growth is normally from 1 to 1.5 cm. per month, but is subject to variation.

B. THE NAILS

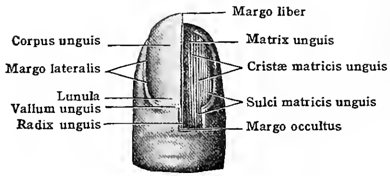
The **nails** [ungues] are thin, semi-transparent, horny epidermic plates upon the dorsal surfaces of the distal phalanges of the fingers and toes. Through their hardness they serve as protective organs not only by covering the nerve endings and other delicate structures of the skin; but also by acting as natural weapons. On the fingers they form useful tools. They are four-sided plates presenting a distal free border [margo liber], which overhangs the tips of the fingers, an irregular, sharp proximal edge [margo occultus], and on each side a somewhat thinned border [margo lateralis] (fig. 1053).

FIG. 1053.—DORSAL SURFACE OF ISOLATED FINGER NAIL. (× 1.) (From Toldt's Atlas.)



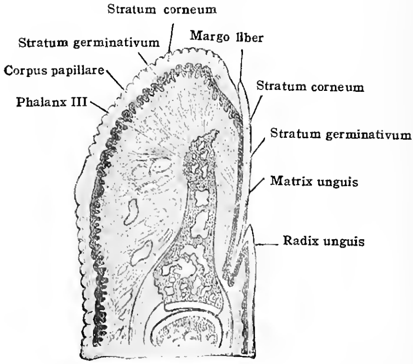
Each nail is composed of an exposed distal part, the **body** [corpus unguis], and a proximal covered part, the **root** [radix unguis], (fig. 1053), which ends in the margo occultus. The nail is at a slightly deeper level than the surrounding skin which overhangs the root and the lateral margins in a fold, the **nail wall**

FIG. 1054.—FINGER NAIL AND NAIL BED.



[vallum unguis] (figs. 1054, 1055, 1056). The epidermis of the free edge of the nail wall, especially proximally, is thickened and often appears as a ragged edge. At a deeper level than the above and extending somewhat more distally is a variably developed thin parchment-like membrane, the **eponychium,** closely attached to

FIG. 1055.—LONGITUDINAL SECTION THROUGH THE TIP OF THE MIDDLE FINGER. (× 2) (From Toldt's Atlas.)

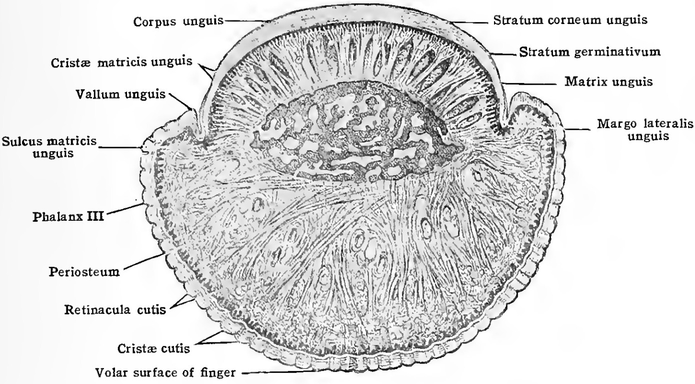


the superficial surface of the nail. It is the representative of the superficial layers of the embryonic epidermis which do not take part in the formation of the nail. The groove which is formed between the vallum and the underlying nail bed is known as the **sulcus matricis unguis.** This lodges the root and lateral margins of the nail and is deepest in the centre of the root, becomes shallower toward the lateral margins, and finally disappears entirely toward the free border of the nail (figs. 1055, 1056).

The dorsal free exposed surface of the nail is formed by a hardened, thickened, horny layer of epithelium corresponding to the deeper parts of the stratum corneum (or the stratum lucidum) of the skin, the **stratum corneum unguis** (fig. 1056). It is convex from side to side (especially on the fifth finger), and also in some cases longitudinally. It presents a number of more or less well-marked fine longitudinal ridges. The stratum corneum forms the principal thickness of the nail. It is thicker and more solid on the toes than on the fingers. The portion of the nail which projects beyond the skin of the fingers and toes is greyish-white in colour. Unless broken or cut, it curves ventrally upon the ball of the finger or toe and tends to become long and claw-like. It may attain a length of 3 or more centimetres.

The concave volar or plantar surface of the nail is softer and is formed of a layer of epithelial cells which corresponds to the stratum germinativum (Malpgihii) of the skin and is known as the **stratum germinativum unguis** (fig. 1056). Because of the transparency of both layers of the nail the blood in the underlying matrix is seen through the body of the nail and gives to it a

Fig. 1056.—Cross-section Through the Nail and Tip of the Ring Finger. (× 4). (From Toldt's Atlas.)



pinkish colour; but toward the root of the nail there is a semilunar area convex distally, the **lunula**, which is less transparent and opaque whitish in color (fig. 1053). The lunula is variously developed in different individuals. It is largest on the thumb and is often absent on the little finger. It is also smaller on the toes than on the fingers.

The stratum corneum unguis consist of thin, flattened, transparent, horny scales with shrunken nuclei. These cells are intimately joined together in thin layers. The stratum germinativum unguis is formed of cells continuous with and resembling those of the corresponding layer of the epidermis. Air may occur between the cells as with the hair. The cells of the root are not yet cornified or dried out.

The stratum germinativum unguis rests upon the corium, which here forms the so-called **nail bed** [matrix unguis].[1] This is made up of a dense feltwork of connective tissue fibres without fat. It is highly vascular and sensitive and the vertically arranged bundles bind the nails tightly to the periosteum of the terminal phalanges. The papillæ of the matrix beneath the body of the nail are arranged in strongly marked longitudinal ridges, the **cristæ matricis unguis.** The cristæ and papillæ of the matrix fit into corresponding depressions on the deep surface of the stratum germinativum unguis.

The cristæ of the matrix are small and low proximally and become larger and fewer distally. Those toward the lateral borders are somewhat oblique. The papillæ of the root are not in rows but are irregularly arranged and disappear entirely near the distal border of the lunula. Toward the free border of the nail the papillæ become large and change in character to that of the adjacent skin.

The best developed nails are those of the thumbs and great toes, the least developed, those of the fifth digits which on the toes are often represented only by a horny tubercle.

Blood-supply of the nails.—The arteries are numerous in the matrix beneath the body of the nail but fewer beneath the root. They pass from the deep parts of the nail bed toward the surface, running in the main longitudinally and sending anastomosing branches to the papillæ.

The **nerves** beneath the nail are abundant and terminate in free sensory endings and in special end organs of several sorts.

[1] The term nail bed is applied by some anatomists to that part of the corium beneath the body of the nail, the term matrix being reserved for the corium beneath the lunula and root.

Development of the nails.—The nails are developed from the epidermis. In early embryos over the dorsal surface of each distal phalanx there is seen a smoother and more adherent area of skin which becomes limited by folds distally as well as proximally and laterally. It is also distinguished by a greater number of cell layers which later become flatter than the surrounding cells. The number of cell layers still further increases and at about the fifth fœtal month the nail proper is formed by the deeper lying cells over au area extending from the proximal fold to the distal end of the lunula. The nail is pushed distally by constant formation of new cells in the same way as it continues to grow throughout life. The surface epithelial cells of the nail field cover the nail for some time as a thin layer, the **eponychium,** which later disappears except a small fringe near the root.

Growth of the Nails.—The nail grows in length and thickness by multiplication of those cells of the stratum germinativum which are situated between the margo occultus of the root and the distal border of the lunula. The older cells are pushed distally and toward the surface by the deeper cells. As a result the nail becomes gradually thicker from the occult border as far as the distal margin of the lunula. Over the rest of the nail bed no thickening appears to take place. The rate of growth is faster on the fingers than on the toes and varies with age, season, and the individual. When the nail is torn off, or detached through inflammation, it may be regenerated if the cells of the stratum germinativum have not been destroyed.

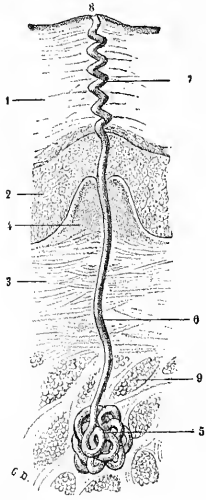
Congenital hypertrophy of the nails sometimes occurs, but absence or imperfect development is rarely seen. The white spots so frequently seen in the nail are caused by air between the cell layers due usually to injury or impaired development.

C. THE CUTANEOUS GLANDS

The **glands of the skin** [glandulæ cutis] are of two kinds: **glomiform glands,** and **sebaceous glands.** The *glomiform* ("skein-like") glands [glandulæ glomiformes] are of four types: sudoriferous glands, ciliary glands, ceruminous glands and circumanal glands.

Fig. 1057.—Vertical Section of the Palmar Skin Showing an Isolated Sudoriferous Gland. (Testut.)

1, Stratum corneum; 2, Malpighian layer; 3. corium; 4, papilla; 5, body of sudoriferous gland; and 6, 7, its excretory duct; 8, orifice of duct on surface; 9, subcutaneous fat.



The **sudoriferous glands** [glandulæ sudoriferæ] or sweat glands are modified simple tubular glands which secrete the *sweat* [sudor]. They are found in the skin of all parts of the body except that part of the terminal phalanges covered by the nails, the concave surface of the concha of the ear, the labia minora, and the inferior part of the labia majora in the female and the surface of the prepuce and the glans penis in the male. The number found in different parts of the body varies greatly. They are very few on the convex surface of the concha and on the eyelid. They are also rather scanty on the dorsal surface of the trunk and neck, more numerous on the ventral surface of these parts and on the extensor surfaces of the extremities, still more numerous on the flexor surfaces, and most numerous on the volar surface of the hands and plantar surface of the feet. They vary from less than 57 to more than 370 to the square centimetre. The total number has been variously estimated at from two to fifteen millions.

Each gland (fig. 1057) consists of a secretory portion or **body** [corpus gl. sudoriferæ], and an excretory **duct** [ductus sudoriferus], which opens on the surface of the skin by a mouth visible to the unaided eye, the so-called 'pore' [porus sudoriferus]. Occasionally the duct opens into a hair follicle.

The **bodies** of the glands are irregular or flattened spherical masses, yellowish or yellowish red in colour and somewhat transparent. They vary in size from .06 to 4 mm. or more with a mean diameter of .2 to .4 mm., the largest being found in the axilla. They are formed of the irregularly, many times coiled, terminal part of the gland tube. The bodies of the glands are situated in the deeper part of the corium or in the subcutaneous tela.

The wall of the rather wide-lumened gland tube is formed of a single layer of cubical or columnar epithelium containing fat and pigment granules and surrounded externally by a basement membrane. Enclosing these is a more or less dense connective-tissue sheath. In many of the glands, especially the larger ones, there is a layer of obliquely running unstriped muscle fibres, the so-called myoepithelium, between the basement membrane and the cells. In some cases the bodies of the glands are imbedded in a more or less dense mass of lymphoid tissue.

The **ducts**, beginning as several coils bound up with those of the bodies, extend often in a straight or slightly wavy course nearly at right angles to the surface as far as the epidermis. This they pierce as spiral canals of from two to sixteen turns, more marked where the epidermis is thickest (fig. 1041), and opened on the surface by somewhat widened funnel-shaped mouths. The ducts pass between the papillæ of the corium and open on the summits of the cutaneous cristæ where these are present. The diameter of the ducts is distinctly smaller than that of the secreting part of the glands, and this is true of the lumen also.

The ducts are lined by a stratified epithelium composed of two, three, or more layers of cells resting on a basement membrane without any intervening layers of muscle-cells, and surrounded by a connective-tissue sheath. This latter as well as the basement membrane ceases at the epidermis and the epithelial cells of the duct walls join those of the stratum germinativum. The duct for the rest of its course to the surface is merely a canal through the cells of the epidermis.

The degree of development of the sweat glands varies with the situation, the individual, and also racially, as instanced by their great development in the negro. In some individuals the perspiration is much more profuse than in others. The glands are smaller in the aged than in the young. The odour of the sweat is peculiar and more or less characteristic, varying with the individual.

The sudoriferous glands in the axillary region seem to be in some way connected with the sexual function for although a large number persist as small glands, others undergo further development beginning about the ninth year in the female and at puberty in the male. These glands in places form almost a continuous layer and are formed of large partly branched tubules with high secreting cells. The reddish colour of the sweat in the axillary and some other regions, especially in certain individuals, is probably derived from the pigment granules which are found in the glands here. The oil in the secretion lubricates the skin and keeps it soft and supple.

Blood-supply of the sudoriferous glands.—The sudoriferous glands are supplied from the deep cutaneous plexus by an abundant network of arteries which surround and penetrate between the coils of the gland tubules.

Nerves.—There is an enclosing network of nerve fibres some of which have been traced to the gland cells.

Development.—The sudoriferous glands are seen first in the fourth or fifth fœtal month. The anlages resemble closely those of the hair, but the cells are not so loosely packed. They project down as solid plugs which become long, slender, and tortuous rods. In the seventh fœtal month the rods begin to develop a lumen in the deeper parts, which also now begin to coil. A lumen soon develops also in the superficial parts and joins that in the deeper part of the gland. The outer of the two layers of epithelium in the ducts becomes transformed at its transition into the gland proper into the myoepithelial layer.

The **ciliary glands** [gl. ciliares; Molli] are modified sudoriferous glands of the branched tubo-alveolar type. They have simpler coils but are larger than ordinary sweat glands. They are situated in the eyelids near their free borders and open into the follicles of the cilia or close to them (see Section VIII).

The **circumanal glands** [gl. circumanales] are found in a circular area about 1.5 cm. wide which surrounds the anus, a short distance from it.

These glands are several times the size of the ordinary sweat glands and resemble the glands found in the axilla, their secretion likewise having a strong odour. They are branching tubular glands. The other kinds of glands which are found in this same area are ordinary sweat glands, glands with straight ducts, with saccules and secondary alveoli, and tubo-alveolar glands.

Cerumimous glands [gl. ceruminosæ] are glomiform glands somewhat modified from the sudoriferous type. They are branched tubo-alveolar glands with relatively large lumina in the coils and narrow short ducts, and occur only in the external acoustic (auditory) meatus.

They are very abundant on the dorsal and superior part of the acoustic meatus in the region of the cartilaginous part, where in the adult most of them open on the surface of the skin close to hairs. Others open into the hair follicles as they all do in the fœtus and child. Their secretion, the **cerumen,** is, when freshly secreted, a fluid or semifluid oily material of a yellowish-brown colour, which on exposure to the air becomes solid like wax.

The **sebaceous glands** [gl. sebaceæ] are simple branched or unbranched alveolar glands distributed over nearly the whole surface of the body. Nine-tenths of them are closely associated with the hairs, into the follicles of which they empty (figs. 1050, 1051), and are therefore absent from certain of the non-hairy parts of the body, as the flexor surfaces of the hands and feet, the dorsal surfaces of the distal phalanges of the fingers and toes. On the other hand, a few are found, usually much modified, opening independent of the hair follicles, as at the angles of the red margins of the lips, around the nares, around the anus, and the *tarsal* (Meibomian) glands in the eyelids. Modified sebaceous glands are also found upon the mammary papilla and areola in the female, and in some cases upon the superficial surface of the glans and the surface of the prepuce of the penis, here known as **preputial glands;** also a few very small ones may be found upon the labia minora, the glans and prepuce of the clitoris.

The glands vary in *size* in different situations and also in individuals and races. They range from .2 to 2.2 mm. long and nearly as broad. Among the smallest are those of the scalp. The largest are found on the alæ of the nose and on the cheeks where their ducts are visible to the unaided eye. They are also large on the mons pubis, labia majora, scrotum, about the anus and on the mammary areola. Smaller glands are also found associated with these large ones. The size of the glands is independent of the size of the hairs with which they are associated but the number of glands depends upon the size of the hair. On small hairs one or more glands are always found and on large hairs there may be a whole wreath of from four to six separate glands opening into the hair follicle.

The *number* of sebaceous glands has never been exactly estimated, although, it is known that they are less numerous than the sudoriferous glands. This is very evident on the extremities, trunk, and neck, where they bear a relation of 1 to 6 or 8. On the scalp, concha of the ear, and skin of the face they are about equal in number while on the forehead, alæ of the nose, free borders of the eyelids and external genital organs in the female the number of sebaceous glands is greater than the number of sudoriferous glands.

Each sebaceous gland consists of a secretory portion, the **body,** connected with the hair follicle or the surface of the skin by a wide short **duct.** In the small glands, the body of the gland may consist of a single alveolus but in the larger glands there are from four to twenty of these connected by irregular ducts to a single excretory duct.

The ducts open into the hair follicles near their necks between the inner root sheath and the hair or upon the surface of the skin. They are always very short, cylindrical, or infundibuliform, and their epithelium is directly connected with that of the outer root sheath of the hair follicle or with the epidermis where the hair is wanting.

The glands lie in the superficial layers of the corium and where one or a few are connected to a single hair, they usually open into the hair follicles on the side toward which the hairs point. Where there are several glands for one hair they may completely surround the hairs like a rosette.

The cells of the body of the gland and of the duct are surrounded by a basement membrane outside of which is a connective-tissue sheath, both of which are continuous with corresponding coverings of the hair follicle.

The periphery of the alveolus is formed of small cubical epithelial cells, the central part of larger and more rounded cells. The cells of the alveolus show all stages of fatty degeneration, the peripheral cells contain small fatty particles, those nearest the centre larger and more numerous fat droplets, some of them being completely broken down. There is no distinct lumen to the alveolus but this is filled with degenerated cells, fatty particles and débris of broken-down and cast-off cells. The deeper cells continue to multiply and push the more superficial cells toward the lumen where they in turn are cast off. The secretion thus formed is known as the **sebum cutaneum.** It is a whitish or whitish-yellow mass composed of fat and broken-down cells of the consistency of thick oil which spreads over the surface of the skin and hair as a lubricant. Through the decomposition of its fat more or less odour is produced. When the gland duct is blocked the secretion is retained and becomes more solid and is known as a **comedo.** The active secretion of the sebaceous glands does not begin before the fifth or sixth year of life. It attains its maximum in the adult and decreases in the aged.

The relation of the arrectores pilorum to the sebaceous glands has been described in connection with the relation of these muscles to the hairs.

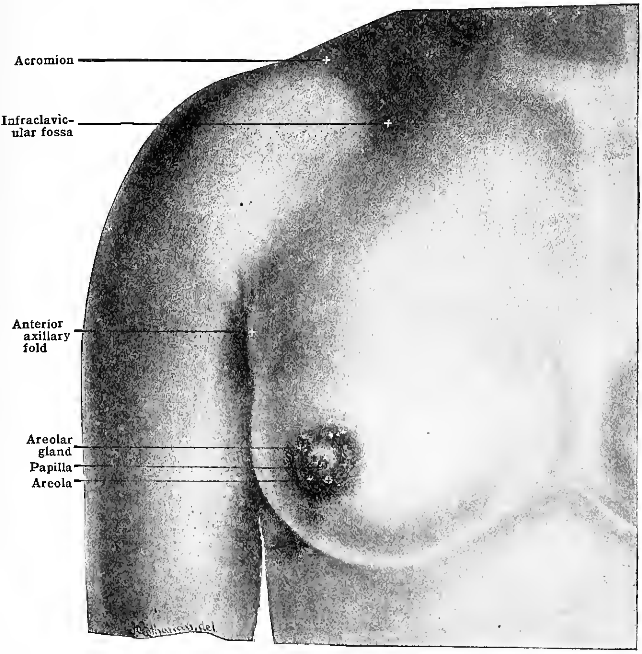
Vessels and nerves.—The sebaceous glands are surrounded by a fine capillary plexus of **blood-vessels** closely associated with those of the hairs and skin. Concerning their **lymph-vessels** little is known. The nerves of the sebaceous glands are connected with those of the skin and hair but the exact manner of distribution is not clearly understood.

Development.—The sebaceous glands appear first in the fifth fœtal month as single, rarely double, buds on the anlages of the hair follicles. The distal ends of these enlarge and become lobulated. In these solid masses of cells lumina for the alveoli and the ducts later are formed, through the fatty degeneration of the central cells. The oily contents of these cells together with the débris and the cast-off surface cells of the epidermis form the **vernix** caseosa on the surface of the fœtus.

D. THE MAMMARY GLANDS

The **mammary glands** [mammæ] or breasts are modified cutaneous glands. In the male they remain rudimentary and functionless throughout life, but in the female they are functionally closely associated with the reproductive organs since they secrete the milk for the nourishment of the newborn and are subjected to marked changes at puberty, throughout pregnancy, during and after lactation, and after the menopause.

Fig. 1058.—The Right Mamma of a Girl 18 Years Old. (Modified from Spalteholz.)



The two mammæ (fig. 1058) are situated on the ventral surface of the thorax one on each side of the sternum. As examined from the surface in a well-developed nulliparous female they appear to extend from the second or third rib to the sixth or seventh costal cartilage and from the lateral border of the sternum to beyond the ventral folds of the axillæ. Separating the two mammæ there is a median unraised area of variable size, the **sinus mammarum.**

In **shape** they are conical or hemispherical, and in consistency somewhat firm and elastic. The **size** of the two breasts is seldom equal, the left, as a rule being slightly the larger. Each measures from 10 to 13 cm. in diameter being slightly longer in the direction parallel to the lateral border of the pectoralis major muscle. The **weight** of each gland varies from 140 to 200 grams, or more.

Each mamma presents for examination a ventral surface and a dorsal surface. The **ventral surface** is free, covered by skin, smooth and convex. It is continuous cephalically, without sharp demarcation, with the ventral surface of the thorax but laterally and caudally it is usually sharply defined (figs. 1058, 1060). It is

Fig. 1059.—The Female Mamma During Lactation. (After Luschka.)

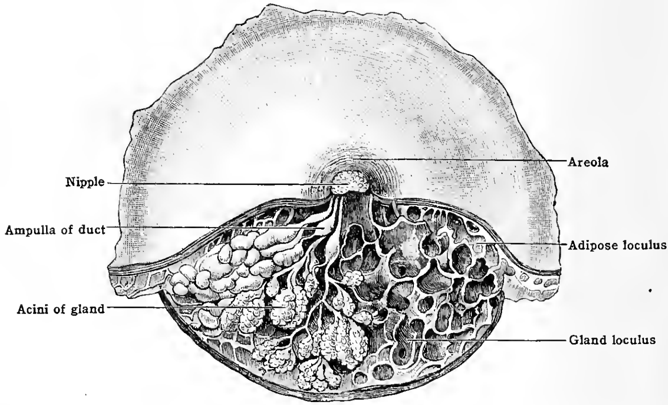


Fig. 1060.—Sagittal Section of the Right Mamma of a Woman Twenty-two Years Old. (Testut.)

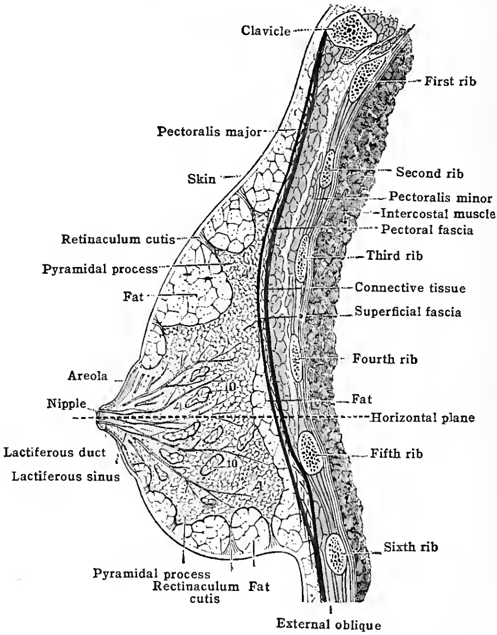
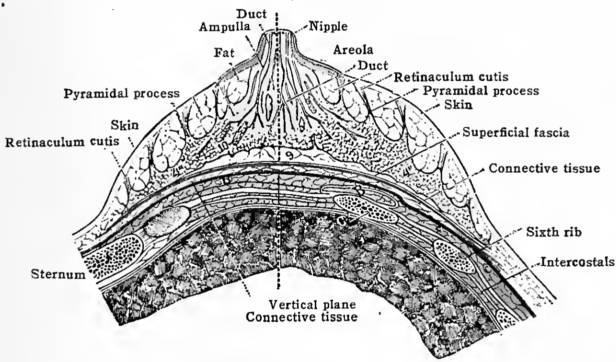


most prominent slightly meso-caudal to the centre and at this point there is a marked pigmented projection, the **nipple** [papilla mammæ] surrounded by a slightly raised area, also pigmented, the **areola mammæ**. These two structures will be described separately later.

The **dorsal surface** of the mammary gland (figs. 1060, 1061) is attached and concave. It is in relation in its cephalo-medial two-thirds with the fsacia over the pectoralis major muscle. In its caudo-lateral third it extends over the base of the axillary fossa, where it is in relation with lymphatic glands and with the serratus anterior muscle, and at its most caudal part, sometimes with the external abdominal oblique muscle.

The usual **number** of breasts in the human species is two; rarely is the number reduced, much more often do we find an increase in this number. Each of these conditions is found in both sexes and may be complete or partial. Complete suppression of both breasts, **amastia,** is one of the rarest anomalies and is usually associated with other defects. Complete absence of one is less rare. A more frequent condition is arrest of development, **micromastia,** leading to rudimentary but functionless organs. Absence of the nipple, **athelia,** is much commoner and generally affects both breasts. All grades of the imperfection from complete absence to slightly imperfect nipple may be found. When there is an increase this may include the whole breast, **polymastia,** or just the nipple, **polythelia.** The supernumerary structures [mammæ

FIG. 1061.—HORIZONTAL SECTION OF THE RIGHT MAMMA OF A WOMAN 22 YEARS OLD. (Testut.)



accessoriæ] may be represented only by a pigmented area representing an areola; or by a nipple with or without an areola; by a gland with a more or less perfect nipple and areola; or with ducts opening without a nipple; or there may be no opening on the surface. The extra mamma is very rarely perfectly developed and functional. Various observers have found the supernumerary breasts or nipples occurring in from 1 to 7 per cent. of the cases examined and somewhat oftener in males than in females. The extra organs are found more frequently on the left side, usually along a line extending from the axilla toward the genitalia. This corresponds to the position in which the mammæ occur in some other mammals and also to the milk line of the embryo. Although they are occasionally found in other situations, over 90 per cent. of them are encountered upon the ventral surface of the thorax along the above-mentioned line caudal and medial to the normal pair of breasts. They are frequently hereditary. It is doubtful whether their possessors are either more fertile or more liable to bear twins.

The **shape** of the breasts varies with the development and functional activity and the amount of fat. The smooth, somewhat conical breast of the nullipara becomes hemispherical with increase in the amount of fat, while in emaciation it may be reduced to a flattened disc with an irregular surface. After lactation the breasts tend to become more pendulous with marked sulci between them and the thoracic walls, and after repeated pregnancies they may become elongated so as to be almost conical or even have pedunculated bases.

The **size** of the mammary gland in girls remains relatively the same as in the infant up to puberty when it suddenly increases considerably and continues for a time to enlarge slightly at each menstrual period. There is also a temporary enlargement and soreness at each menstrual period, due perhaps to the increased vascular supply. Until the age of puberty the glands measure 8 to 10 mm. in diameter but when they have attained their complete adult development they have increased to 100 to 110 mm. in the cephalo-medial, 120 to 130 mm. in the cephalo-lateral (obliquely from above downward) direction, and 50 to 60 mm. in thickness. During pregnancy the breasts again increase in size, more especially after the birth of the child. When their full functional activity is established, their volume may be two or three times as great as before pregnancy. After lactation they return again nearly to their former size, which they retain until another pregnancy. After the menopause the useless glands in some cases atrophy and are reduced to small discoidal masses. In others, especially in fat individuals, although the secretiug tissue disappears, it is replaced by fat so that there is little or no reduction in size. In addition to the above-mentioned variations in size, the breasts are subject to great individual differences, the cause of which is little understood. Large robust women are sometimes seen with small mammary glands, and small women with large glands. In some individuals they are especially large.

The **weight** of each mamma varies, naturally, with the volume, increasing from 30 to 60 centigrams in the small gland of a young child to 140 to 200 grams after puberty and in nursing women reaching 400 to 500 and occasionally 800 to 900 grams.

The firm and elastic, well-developed breasts of young nulliparæ become during lactation even more firm and tense, but after lactation especially if there has been a long period of nursing they lose their consistency and after several pregnancies become soft and flabby.

The sulcus which defines the caudal border of the breast is but little marked in thin nulliparæ, more marked in fat women, and especially evident in some multiparæ. The relations of the dorsal surface of the gland vary somewhat with the position. The level varies with the stature; as a rule, in tall women it is more caudal and in short and broad-chested women it is more cephalic. The tightness of the attachment to the sheath of the pectoralis major muscle is quite variable, but even when quite loose there is some movement of the breast when the arm is raised. The glandular tissue of that part of the breast which overhangs the axilla may be in direct contact with the lymphatic glands.

Structure.—The mammary glands are composed of the essential epithelial glandular tissue, the **parenchyma,** the supporting and enclosing connective tissue of the subcutaneous tela, the **stroma,** and the covering cutaneous layer.

Parenchyma.—The essential part of each mamma is a flattened, circular mass of glandular tissue of a whitish or reddish-white colour, the **corpus mammæ.** This is thickest opposite the nipple and thinner toward the periphery. The ventral surface of this mass is convex and made uneven by numerous irregular pyramidal processes which project toward the skin. The dorsal surface, or base, is flat or slightly concave and much less irregular than the ventral surface. Minute processes of glandular tissue extend from the corpus mammæ into the retromammary tissue, some of them accompanying the septa of the pectoral fascia between the bundles of muscle fibres of the pectoralis major muscle. The circumference of the mamma is thick and well defined, more marked caudally than cephalically, but it presents numerous irregular processes which extend beyond the limits apparent from the surface. One of these especially large and well marked extends cephalolaterally into the axillary fossa, and there are frequently other large but less-marked projections.

The **corpus mammæ** is not a single structure but is composed of from fifteen to twenty separate **lobes** [lobi mammæ] (fig. 1059). These are larger and smaller irregular flattened pyramidal groups of glandular tissue, with their apices toward the nipple and their bases radiating toward the periphery of the gland.

Each lobe has a single excretory **duct** [ductus lactiferus] (figs. 1059, 1060, 1061), which opens by a contracted *orifice* [porus lactiferus] in a depression upon the tip of the nipple. When traced from the pore toward the circumference of the gland, the ducts are seen to run first directly dorsally through the nipple, parallel and close to one another. From the base of the nipple they diverge. Each duct is here visible to the unaided eye and measures from 1.5 to 2.5 mm. in diameter. Beneath the areola its diameter increases for a short distance to from 4 to 9 mm., forming thus a reservoir, the ampulla or **sinus lactiferus,** in which the secretion may accumulate for a time. Beyond this dilation the duct continues. gradually decreasing in size as it breaks up into smaller and smaller branches, There is no anastomosis between the ducts during their course, although at or beneath the pore two or more ducts may join to have a common opening. They possess no valves but when empty their inner surface is thrown into longitudinal plicæ.

The ducts have an external coat of white fibrous connective tissue mixed with circular and longitudinal elastic fibres. They are lined with a simple cuboidal or columnar epithelium, except near the orifice, where it is stratified squamous. External to the lining epithelium there occurs in the smaller ducts a second layer of elongated cells resembling the myoepithelium of the sudoriparous glands.

Each of the terminal branches of a duct ends in a tubulosaccular, spherical or pyriform **alveolus.** A number of these alveoli which open into a common branch of the duct, when grouped together and bound up with connective tissue, constitute a **lobule** of the gland (lobulus mammæ). A lobe is made up of all the lobules whose ducts join one common excretory duct.

The alveoli are composed typically of a single layer of epithelial cells enclosed by a basement membrane. This layer is the true secretory epithelium. It consists in the more active gland of granular polyhedral or cuboidal cells which may be so closely placed as to leave almost no lumen to the alveoli. During lactation these cells may be found in different stages of secretory activity, their central ends being filled with minute oil globules and more or less flattened according to the degree of distention of the alveoli. The alveoli and ductules now possess considerable lumina which are filled with the above-mentioned milk globules liberated from the cells and suspended in a serous fluid also secreted by the cells. This constitutes the *milk* (lac femininum).

Stroma.—The lobes, lobules, and alveoli are completely covered by a connective-tissue sheath too delicate to constitute a distinct capsule. Outside of this the whole gland is embedded in the subcutaneous tela which forms for it a sheath, **capsula adiposa mammæ.** This is particularly well developed on the ventral surface where the fat fills in between the irregularities caused by the lobes and lobules and gives to the surface of the gland its smooth appearance. Within the corpus mammæ there is little fat between the lobules in nulliparæ but much more fat is found here in the stroma in multiparæ. When the fat is absorbed, as it is during lactation and in emaciation, the lobules stand out much more distinctly. There is however, no fat immediately beneath the areola and nipple. The connective tissue is here loosely arranged and allows free motility of the nipple and also permits the more easy distention of the ducts and sinuses during lactation. The connective-tissue strands, **retinacula mammæ,** which extend from the apices of the glandular processes on the ventral surface of the mamma are connected to the corium and correspond to the retinacula cutis found in other situations. These are sometimes particularly well developed over the cephalic part of the mamma and have been called the *suspensory ligament of Cooper*.

The dorsal surface of the mamma is bound to the pectoral fascia by loose connective tissue containing, as a rule, only a small amount of retromammary fat (figs. 1060, 1061). The attachment to the sheath of the pectoralis major muscle is at times so loose that the spaces between the connective tissue appear to form serous sinuses, the **sub- or retromammary bursæ.**

In addition to the axillary process or 'tail' of the gland, a projection is sometimes seen extending toward the sternum and another caudolaterally; also processes extending toward the clavicle and caudomedially have been described. Besides these large projections there are numerous branched interlacing processes which combine into larger and smaller masses on the ventral surface and exist as minute extensions on the dorsal surface. In thin women, the parenchyma at the apex of these triangular processes reaches nearly to the surface.

A mammary gland may be made up of a larger amount of stroma and a smaller amount of glandular tissue, or the reverse, and therefore a small breast may furnish more milk than a large one. There is also a variation in different parts of the same breast, one lobe or section may have well-developed lobules while in another they remain almost as at puberty, merely branching ducts.

The glandular tissue when sectioned is whitish with a greyish or pinkish cast and is firm and resistant, almost cartilaginous in consistency. It is thus easily distinguished from the adipose capsule.

Changes due to age and functional activity.—At birth the mamma consists mainly of fifteen to twenty slightly branched ducts lined with stratified squamous or columnar epithelium. In spite of the lack of true glandular tissue, within the first few days there may be such rapid cell proliferation that the ducts become distended with cells and detritus. By pressure upon the gland a few drops of this material may be expressed which constitutes the so-called 'witches milk.' From birth until puberty the mamma remains rudimentary, simply keeping pace with the general body growth, but in the female, at puberty, an abrupt change occurs. The tubules grow rapidly into the surrounding tissue and some acini (alveoli) appear; the stroma and fat are also greatly increased; and the breast becomes rounded and well formed but consists mainly of fatty stroma and ducts, with but a very small number (if any) of true secreting acini. At this time in both boys and girls the breast may become swollen and tender and a milk-like secretion may be produced similar to that at birth. The great increase in volume during pregnancy and lactation is due to the increase in the size and number of the lobules and acini, and is accompanied by a decrease in the interlobular and intralobular stroma and in the fat, so that the gland feels hard and uneven. The acini appear first in the periphery, thence along the larger ducts toward the centre of the corpus mammæ.

The secretion of the gland for the first two or three days after parturition until the free secretion of milk is established is termed the **colostrum.** It differs from normal milk not only in chemical composition but also in containing larger fat globules and special cells known as **colostrum corpuscles.**

The decrease of the gland nearly to its original size after lactation is due to an *involution* of the parenchyma, the acini being reduced to narrow tubules, most of them completely atrophying. With this is associated a development of fat and fibrous stroma. The gland does not, however, regain its virgin appearance but its main mass is looser and more irregular, less distinct, and the peripheral processes larger, while the stroma contains numerous fat-lobules. This causes the breast to be less smooth, firm, and elastic, and it tends to become pendulous and form a sulcus where it overhangs its base. With the end of sexual activity the secreting portions of the glands gradually atrophy, finally leaving little more than the ducts. Even these undergo senile atrophy, and the main mass of the gland is represented only by a flattened disc, in which the peripheral processes can scarcely be made out. In fat women there may be little reduction in size, but the breast is here transformed almost entirely into fat.

The **skin** covering the ventral surface of the breast is very white, covered with lanugo hairs associated with sebaceous glands, and contains many sweat glands of the ordinary type. It is so thin that the subjacent veins are readily seen through it. It is closely adherent to the subjacent fatty layer but its flexibility, elasticity, and motility over the deeper glandular tissue permit much stretching during the enlargement which occurs at the time of lactation. In spite of this, **linea albicantes** are often produced especially when the breasts have been unusually large. Aside from the above-mentioned particulars it does not differ from the skin of the adjacent part of the thorax, except over the centre of the breast where it forms the areola and nipple.

The **areola mammæ** (figs. 1058, 1059, 1060, 1061) is covered by a thin, delicate, pigmented skin. The *colour* in young nulliparæ is reddish, the shade varying with the complexion. During pregnancy the colour darkens, slightly in blondes, but so as to become almost black in marked brunettes.

This pigmentation serves as one of the signs of gestation. After lactation the colour fades, but little pigmentation remaining in blondes, considerable in brunettes. During pregnancy there is sometimes seen extending more or less beyond the areola a less deeply and less uniformly pigmented ring, the **secondary areola.** In size, the areola is subject to considerable individual variation and is increased in pregnancy.

The *surface* of the areola is roughened by a number of slight *elevations* irregularly arranged. These are due to underlying large sebaceous and rudimentary milk glands [gl. areolares; Montgomerii], tubercles of Montgomery. Projections caused by sebaceous glands are also found in the secondary areola. All of these tubercles enlarge greatly during pregnancy and the glands produce a slight secretion which is discharged through ducts that open on their summits. The sweat glands are few but large, and in addition to the lanugo hairs there are usually several well-developed hairs.

The *corium* of the areola is devoid of fat but contains a well-developed layer of smooth muscle fibres, the fascicles of which intercross in various directions but may be seen to be mainly of two orders, circular and radial. They are continuous with those of the nipple. The circular fibres are most numerous adjacent to the nipple, where they may form a layer nearly 2 mm. in thickness.

The areola varies greatly in size, measuring from 15 to 60 mm. in diameter. There is some confusion in regard to the areolar glands and the tubercles of Montgomery. Some consider the tubercles to be caused by the areolar glands, others consider them caused by the sebaceous glands. Sebaceous glands undoubtedly cause the projections in the secondary areola. The sudoriferous glands of the areola are large and compound tubular glands with a complicated glomerulus and are considered as transitions between sweat and mammary glands. The sebaceous glands are even more numerous than the sudoriferous and are composed of several lobes. They also have been considered by some as intermediate stages in the formation of mammary glands, but this is improbable. There are ten to fifteen very small areolar glands (though Pinard found an average of but four to each breast), whose structure is essentially identical with that of the principal mammary glands. They have dilations on their ducts and they open on the areola at times in common with a sebaceous gland.

The **nipple** [papilla mammæ] (figs. 1058, 1059, 1060, 1061) in well-developed nulliparæ is situated slightly meso-caudal to the centre of the breast and on a level with the fourth rib or fourth intercostal space about 12 cm. from the median line. But its position in reference to the thoracic wall varies greatly with age, individual, and the present and past activity of the gland. The nipple is usually somewhat conical or cylindrical with a rounded fissured tip marked by fifteen to twenty minute depressions into which the lactiferous ducts empty. The average length of the nipple is 10 mm. to 12 mm. The skin is thin, wrinkled, and pigmented like the areola, except over the tip of the nipple where there is no pigment.

The **corium** of the nipple has many large vascular and nervous papillæ and there is no fat in it. Hairs and sudoriferous glands are absent but sebaceous glands are present in great numbers. Their secretion here and over the areola serves to keep the skin soft and to protect it from the saliva of the nursing infant. In the deeper layers of the corium smooth muscle fibres form a loose stratum continuous with that of the areola. This is made up principally of an external circular layer and to a slight extent by an internal layer whose bundles of fibres are parallel with the milk ducts. Numerous interlacing muscle fibres connected with these layers and mixed with loose connective tissue, and elastic fibres, but no fat, surround the lactiferous ducts as they pass through the axis of the nipple.

The nipple usually does not project from the surface until the third year. It soon becomes conical but does not attain its full size until shortly after puberty. The size of the nipple is variable, ordinarily in proportion to the size of the gland, but large nipples are sometimes found on small breasts and small nipples on large breasts. During pregnancy the nipple increases in size and becomes more sensitive and more easily erectile. The shape of the nipple in addition to conical or cylindrical may be hemispherical, flattened, discoidal, or slightly pedunculated. Its end may be invaginated or the entire nipple retracted beneath the surface of the gland and projecting only in response to stimuli.

The circular muscle fibres of the nipple act like those at its base in the areola. By intermittent, rhythmic contractions they tend to empty the lactiferous ducts; by continuous and tight contraction they act as a sphincter. When contracted they also narrow the nipple, make it harder, erect, and more projecting. When the vertical fibres contract they depress the tip of the nipple or they may retract the whole nipple beneath the surface. The muscle of the areola when stimulated puckers the skin toward the nipple causing circular concentric folds in the skin of the areola.

The **male mammary gland** [mamma virilis]. This develops exactly as with the female. From birth to puberty the glands in the two sexes have a parallel growth and development, but from this time on the glands in the male grow but slightly and reach their full development about the twentieth year.

The corpus mammæ in the adult male measures from 1.5 to 2.5 cm. in diameter and .3 to .5 cm. in thickness. It is whitish in colour, tough, and stringy. It is composed of the same number of lobes as in the female but these consist of little more than short ducts with no true acini and may be reduced to mere epithelial or connective-tissue strands. The areola and nipple are present and pigmented, but the nipple averages only 2 to 5 mm. in height. The areola has a diameter of 2 to 3 cm. and is covered with hairs. The areolar tubercles may be recognised and the areolar muscle is present. The position of the nipple in relation to the chest-wall is more constant than in the female as the breast is less movable. It is seldom beyond the limits of the fourth intercostal space or the two adjacent ribs, and averages 12 cm. from the median line. Occasionally the male breast may hypertrophy on one or both sides, **gynecomastia.**

Blood-supply.—The main arterial supply to the mammary gland is from mammary rami of perforating branches of the internal mammary artery (p. 567). Usually that from the second or third intercostal space is especially large. Small branches, external mammary rami, are also supplied to the caudal and lateral segments of the breast by the lateral thoracic artery (p. 571). Some rami from the thoracoacromial or supreme thoracic arteries (p. 571) may reach the cephalolateral segment of the breast and small twigs, lateral mammary rami, from the anterior branches of the lateral cutaneous rami of the aortic intercostal arteries (p. 589) supply its deep surface.

These vessels anastomose freely and form a wide-meshed network in the stroma of the ventral and dorsal surfaces from which branches proceed around the lobes and lobules and finally form a close network of capillaries around the alveoli. From these, venous capillaries arise and pass in two groups, one deep, accompanying the arteries, the others superficial. These latter extend to the ventral surface of the gland to form a loose network beneath the skin. During lactation these subcutaneous veins show through the skin as bluish lines, and frequently form a more or less complete circle around the nipple. They connect with the superficial veins of the neck superiorly, with those of the abdomen inferiorly, and with the thoracoepigastric vein laterally. The deep veins carry the blood to larger vessels, which empty into the subclavian, the intercostal, the internal mammary, and the axillary; and the superficial group may connect with the external jugular and femoral veins.

The lymphatics.—The lymphatics of the mammæ are extremely numerous, forming rich plexuses and free anastomoses. Their exact origin and distribution are not yet fully understood, but it is clear that there is a rich plexus in the skin of the areola and nipple which empties mainly into a subareolar plexus. Deep lymphatics arise in the spaces around the alveoli in all parts of the gland, and most of these converge toward the nipple where they join the subareolar plexuses. They anastomose freely with the cutaneous lymphatics and many of them empty into the subareolar plexus through large lymph-vessels which run parallel with the lacteal ducts. From the subareolar plexus usually two large lymph-vessels arise and pass toward the axilla to empty into the axillary lymph-glands (p. 719). Other lymphatic vessels of the mammary gland follow the course of the various blood-vessels.

There is usually a third trunk from the cephalic part of the breast and often a fourth from the caudal segment which join with the others to the axillary glands. The lymphatics of the mammary gland also communicate with the lymphatics of the skin, the ventral chest-wall and those of the deep fascia over the pectoral muscles, as well as the lymphatics of the opposite side. They also empty into the lymphatics which accompany the blood-vessels of this region, and thus communicate with the axillary, subclavicular, and supraclavicular lymphatic nodes (p. 722). Moreover, those from the medial portion of the gland accompany the branches of the internal mammary artery and empty into the sternal glands along the artery within the thorax. Since cancer of the breast extends and is disseminated through lymphatic channels, their distribution and connections are of great practical importance.

The nerves.—The gland proper receives its nerves laterally from the **lateral mammary rami of the anterior rami of the lateral cutaneous branches of the fourth to sixth intercostal nerves** and medially from the **medial mammary rami of the anterior cutaneous branches of the second to the fourth intercostal nerves.** The skin over the breast receives in addition to branches from the above nerves, branches from the **supraclavicular nerves** of the cervical plexus. It is altogether probable that sympathetic fibres reach the gland but by what course is not yet clear. The nerves are distributed in part to the skin, in part to the plain muscle of the areola and nipple, some to the blood-vessels, and others to the glandular tissue. The secretion is, however, not entirely controlled by nerves as it is influenced also by hormones from other organs brought to it by the blood.

Development.—In very early embryos the epithelium over an area on the side of the body extending from the fore to the hind limb (or beyond these limits) is seen to be deeper and more cubical, the mammary streak. In this area there is produced by multiplication of cells a ridge, the *mammry line or ridge.* In spots along this line, corresponding to the relative position of the mammary glands in some mammals and the supernumerary mammæ in man, the epithelium thickens. The intervening parts of the line disappear as the spots enlarge to form transient *mammary hillocks.* In man ordinarily development proceeds in but one of these hillocks on each side. The deep surface of the hillock projects into the corium as the superficial surface flattens out and the mesodermic cells of the corium condense around the ingrowth producing the *nipple zone.* Rapid proliferation of the deeper cells produces a *club-shaped stage* from the deeper surface of which small bud-like masses of epithelial cells sprout and extend as solid plugs into the corium. These are the anlages of the true secreting part of the gland and the number of buds corresponds to the number of lobes of the future gland. The sprouts extend beyond and beneath the nipple zone and are supported by closely packed connective-tissue cells forming the *stroma zone.* The epithelial buds continue to grow and branch and a lumen is finally produced in the originally solid plugs. The primary epithelial ingrowth degenerates and ultimately disappears. A cavity is produced in it which later connects with the lumina of the gland ducts. The depressed nipple zone becomes elevated above the surface soon after birth. Further development of the mammary gland has been discussed previously under changes due to age and functional activity (p. 1303).

THE DUCTLESS GLANDS

Under the term *ductless glands* are included not only certain glandular structures of epithelial origin with a more or less definitely known function and an internal secretion but also certain organs whose function is not definitely known or understood. Of the organs here considered, the function of the thyreoid gland, the parathyreoid glands, the chromaffin system, the medullary portion of the suprarenal glands, and the aortic paraganglia is somewhat definitely known. But the function of the thymus, the spleen, the cortical portion of the superenal glands, the glomus caroticum, and the glomus coccygeum is still in doubt; although probably some, if not all of them, have an internal secretion or at any rate are closely associated with the other glands of internal secretion. The hypophysis and the pineal body are not considered in this connection but will be found described with the brain (pp. 845, 848). The lymph-nodes, which may also be considered as ductless glands, are described in Section VI. Many of the true glands, such as the liver, pancreas and sexual glands, have also internal secretions which pass directly into the vascular system as in the ductless glands.

THE SPLEEN

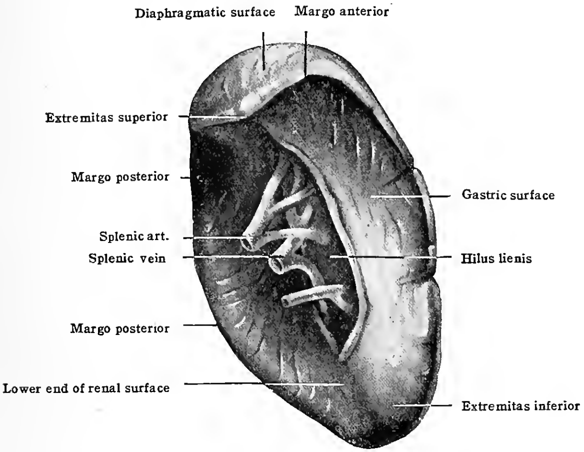
The **spleen** [lien] is a large blood-vascular organ closely associated with the lymphatic system. Its exact function is still in doubt.

Position.—The spleen is situated in the dorsal part of the left cephalic segment of the abdominal cavity so deeply placed against the diaphragm and dorsal to the stomach and colon as to be invisible from the ventral surface of the body when the abdominal cavity is opened. It is mainly in the left hypochondriac region but its deepest and most cephalic part extends also into the epigastric region. It is obliquely placed with its long axis corresponding approximately to the line of the caudal ribs. It tends to become more vertical when the stomach is fully distended but when the stomach is empty and the colon distended it assumes a more horizontal position. Changes in the attitude of the body also cause slight alterations in the situation of the spleen. It moves with the excursions of the diaphragm in expiration and inspiration.

The **colour** of the spleen is, in life, a dark bluish-red or brownish-red, but after death it becomes darker with a more bluish or violet tint.

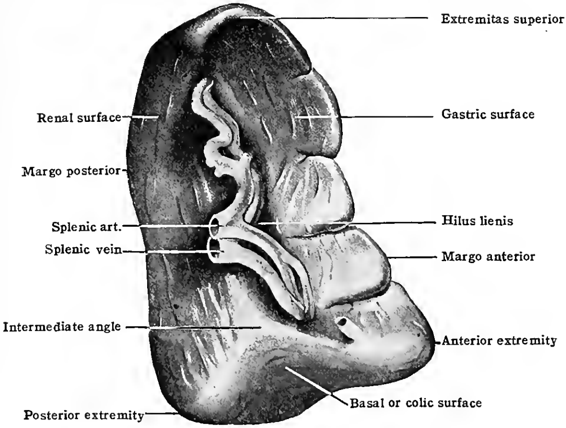
The **size** of the spleen is perhaps more variable than that of any other large organ in the body. Not only does the size differ in different individuals but it changes greatly with the blood content in the same individual. There is a distinct expansion for a time after each meal and the spleen contracts and expands rythmically.

Fig. 1062.—Wedge-shaped Spleen, Visceral Surface.



In the adult it usually measures 10 to 15 cm. in length, 7.5 to 10 cm. in breadth, and 2.5 to 4 cm. in thickness. The weight usually ranges from 150 to 225 gm. At birth it represents from $\frac{1}{320}$ to $\frac{1}{400}$ of the total body weight and this porportion is maintained without much variation until the age of fifty years, when (like the lymphoid organs in general) it begins to diminish

Fig. 1063.—Tetrahedral-shaped Spleen, Visceral Surface.

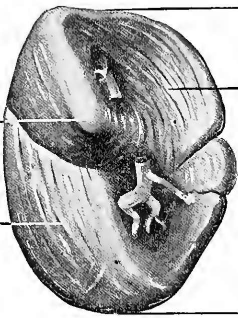


in size. This diminution continues until in the very old it represents but $\frac{1}{700}$ of the body weight. There is no great difference in relative size in the two sexes.

The spleen is somewhat soft and very friable. It is elastic, extensible, contractile, and extremely vascular.

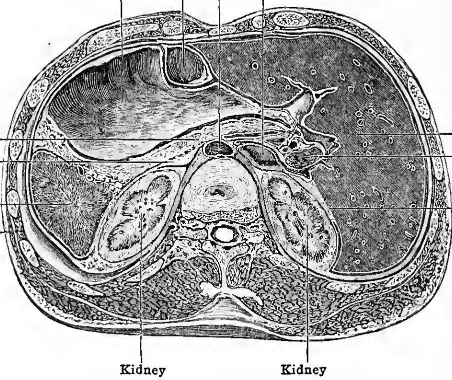
Shape.—In form the spleen varies greatly. This is due largely to its softness which permits considerable modifications by the pressure of the distended or contracted surrounding hollow viscera. When *in situ* with the stomach distended, its shape may be compared to a blunt spherical wedge with a concave apex and rounded extremities, and possessing therefore three surfaces (fig. 1062); but when the stomach is contracted and the left flexure of the colon distended an additional surface is produced and its shape becomes tetrahedral (fig. 1063). Inter-

FIG. 1064.—SPLEEN SHOWING TUBERCLE ON THE INTERMEDIATE BORDER.



mediate forms between these extremes are produced by variations in the degree of distention of stomach and colon. The spleen presents two aspects: lateral or *parietal,* against the diaphragm; and medial or *visceral,* toward the abdominal cavity. In its usual wedge form the three surfaces of the spleen are diaphragmatic, gastric, and renal. There are three borders, anterior, posterior, and intermediate; and two extremities, superior and inferior.

FIG. 1065.—CROSS-SECTION OF THE BODY AT THE LOWER PART OF THE EPIGASTRIC REGION. (Rüdinger.)



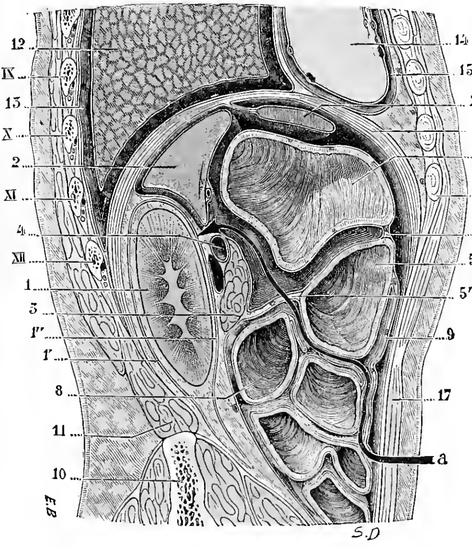
The **diaphragmatic surface** [facies diaphragmatica] is a smooth convex surface with an irregularly oval outline, in the wedge-shaped spleens wider cephalically, but in the tetrahedral-shaped spleens wider caudally. It looks dorsally toward the left and somewhat cephalically.

It lies against the diaphragm over an area opposite the ninth, tenth, and eleventh ribs and the intervening intercostal spaces, with its long axis corresponding in a general way to the course of the ribs. Although it is separated from the ribs by the peritoneum, the diaphragm, and the left pleural cavity (cephalically also by the left lung) (figs. 1065, 1066), the ribs sometimes make impressions upon it.

The **gastric surface** [facies gastrica] is a semilunar-shaped surface, concave cephalo-caudally and from side to side, which looks ventrally to the right and somewhat caudally (figs. 1062, 1065, 1066). Nearly parallel with the dorsal boundary of this surface is a narrow depression usually formed by a series of pits, as a rule six or eight, which together form the **hilus** of the spleen [hilus lienis]. In this situation the vessels and nerves enter and leave the spleen, the vein being dorsal.

When the stomach is distended it is in contact with the major part of the gastric surface, the left flexure of the colon forming an impression upon a small area near the caudal extremity and the tail of the pancreas, as a rule, resting against a narrow area dorsal to the hilus or just

Fig. 1066.—Sagittal Section through the Left Side of the Body, Showing the Relations of the Spleen. IX, X, XI, XII, corresponding ribs. 1, Left kidney; 2, spleen; 3, pancreas; 4, splenic vessels; 5, transverse colon; 6, stomach; 7, left lobe of liver; 12, lung; 14, heart; 16, diaphragm. (Testut and Jacob.)



cephalic to the colon. When the stomach is empty and contracted and the colon distended the size of the gastric area is considerably decreased and the relative size of the colic impression greatly increased so as to form upon the spleen in this situation a colic or basal surface (fig. 1063). The stomach is, however, at all times in contact with some part of the spleen.

The **renal surface** [facies renalis] the smallest of the three surfaces, shorter as well as narrower than the gastric surface, is an oblong, flat or slightly concave area, which faces dorsally, to the right and slightly caudally. It is in relation with the anterior surface of the left kidney (fig. 1066).

In some cases the cephalic third of the renal surface is also in relation with the anterior surface of the suprarenal gland. It is separated from these latter structures, however, by the renal adipose capsule as well as by the peritoneum. The tail of the pancreas in some cases is in contact with a small area on the ventral part of this surface. In fat individuals these relations are not as intimate as the relations with other organs because of the large amount of suprarenal fat.

The **anterior border** [margo anterior] is clearly defined, thin, sharp, and more or less convex. It is marked in over 90 per cent. of the cases by one or more transverse or oblique notches, especially in its cephalic part. It is placed between the diaphragm and the stomach and separates the diaphragmatic from the gastric surface (figs. 1062–1065).

The **posterior border** [margo posterior] is rounded, shorter, and straighter than the anterior border and is notched in less than a third of the cases. It separates the diaphragmatic from the renal surface and is lodged in the angle between the left kidney and the diaphragm (figs. 1062–1065).

The **intermediate border** is a blunt ridge dorsal to the hilus, separating the gastric from the renal surface.

It may be clearly defined or more or less obscure and often shows a marked tubercle (fig. 1064). When the stomach is contracted and the colon distended this border divides caudally into ventral and dorsal limbs both of which may be well marked or either may be deficient depending on the direction and degree of pressure of surrounding organs. When well marked there is produced at the point where the two limbs diverge a more or less marked projection, the intermediate extremity or angle (fig. 1063).

The **superior extremity** [extremitas superior], usually larger than the inferior extremity in the wedge-shaped spleens but smaller in the tetrahedral form, is rounded and bent medially. It extends as high as the tenth thoracic vertebra and lies 1 to 2 cm. from the vertebral column.

The **inferior extremity** [extremitas inferior], also somewhat rounded, is directed toward the left and caudally. It is in relation with the phrenicocolic ligament.

When the stomach is contracted and the colon distended the inferior extremity becomes much broader, in extreme cases forming a distinct **inferior border** ending ventrally in the anterior margin as an **anterior extremity** and dorsally in the posterior margin as the **posterior extremity** (fig. 1063).

In the **tetrahedral-shaped spleen** the additional surface produced by the pressure of the colon is known as the **basal** or **colic surface** (fig. 1063). This varies in size reciprocally with the degree of pressure of colon and stomach.

When well developed the colic surface is concave and is separated from the renal and gastric surfaces by the more or less sharply defined dorsal and ventral limbs of the intermediate border and separated from the diaphragmatic surface by an inferior margin produced from the broadened inferior extremity. The left flexure of the colon is in contact with the greater part of this surface, but the pancreas also usually lies against it in its cephalic part (fig. 1063).

Peritoneal relations.—The surface of the spleen is completely covered, except for a small area at the hilus, by a peritoneal coat, the **tunica serosa.** Ventral to the hilus a double layer of peritoneum is prolonged from the spleen to the left side of the greater curvature of the stomach and the left edge of the ventral layer of the great omentum, forming the **gastrolienal ligament** which contains the short gastric arteries and veins. Dorsally a second double layer of peritoneum extends from the hilus to the ventral surface of the kidney and the caudal surface of the diaphragm forming the **phrenicolienal** (lienorenal) **ligament.** This ligament encloses the splenic artery and veins as they pass to and from the spleen. It is also between the two layers of peritoneum of this ligament that the tail of the pancreas reaches the spleen (fig. 1065). Except by these two ligaments the spleen has normally no attachment to the abdominal wall or to any of the surrounding viscera. The gastrolienal, and more especially the phrenicolienal ligament, serve in a measure to anchor the spleen in its place in the abdominal cavity but in addition to these the spleen is supported by a fold of peritoneum which extends from the left colic flexure to the parietal peritoneum over the diaphragm, the **phrenicocolic ligament.** This serves as a sling in which the inferior extremity of the spleen rests. The spleen, however, is held in position in the abdominal cavity mainly by the intraabdominal pressure.

Topography.—The superior extremity of an average-sized spleen is located between the angle and tubercle of the tenth rib on the left side and about 3 to 4 cm. from the median line on a level with the spinous process of the ninth thoracic vertebra. In the majority of cases, it does not extend more than 2 cm. either cephalic or caudal to a transverse plane at the level of the infrasternal notch. The inferior extremity reaches nearly to the midaxillary line in the tenth intercostal space and 10 to 15 cm. from the superior extremity. The long axis therefore corresponds nearly to the shaft of the tenth rib. The posterior border lies beneath the cephalic border of the eleventh rib. The whole spleen (unless enlarged) lies dorsal to a plane passed through the midaxillary lines and is lateral to a line from the left sternoclavicular joint to the tip of the left eleventh rib. In deep inspiration the spleen is greatly depressed and if enlarged may be felt beneath the ribs.

Variations.—From the mean weight between 150 and 200 gm. there are wide variations. It is not rare to find spleens weighing 80 to 100 gm. and they are recorded as light as 10 and

20 gm. On the other hand, spleens weighing 3000 to 4000 gm. are sometimes found. These are usually, however, associated with an acute infectious disease, such as malaria or typhoid fever, or a progressive metamorphosis, such as leukemia.

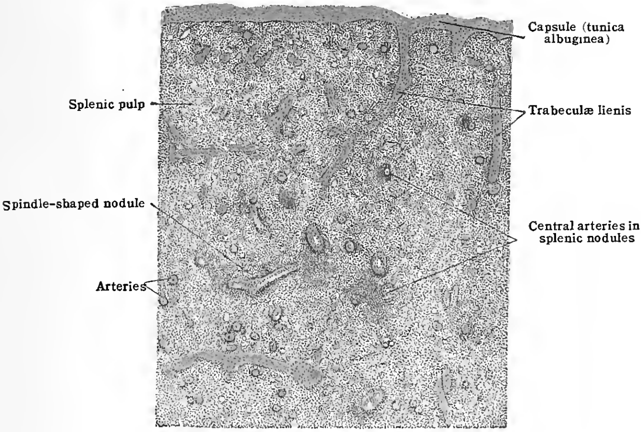
Congenital *absence* of the spleen is one of the rarest anomalies. The presence of more than one spleen is the commonest anomaly of the spleen. Adami has found accessory spleens to occur in 11 per cent. of all autopsies. They are round or oblong and vary in size from a pea, or smaller, to a walnut. There are most often one or two but there may be twenty or more. They are found near the hilus on the dorsal side of the gastrolienal ligament, less often, in the great omentum, in the mesentery, on the wall of the intestine, or in the tail of the pancreas.

In certain cases the left lobe of the liver is very long and prolonged far to the left and separates the spleen from the diaphragm. This is the rule in the fœtus and is often found in the infant but is exceptional in the adult.

Exceptionally the spleen may be placed far caudal to the normal situation extending into the iliac region and even into the pelvis. This is due in part to congenital laxness of the supports, also to increase in weight. The spleen has been found in almost every part of the abdominal cavity and in transposition of the viscera it is upon the right side.

One or more **notches** on the anterior border are present according to Parsons in 93 per cent. of the cases, two or more in 66 per cent., but five, six, or seven much more rarely. On the posterior border notches are found in 32 per cent. of the cases, and on the inferior border in 8 per cent. In 20 per cent. of the cases a marked fissure, occasionally more than one, is found on the diaphragmatic surface. Most frequently it begins at one of the notches in the posterior border and passes for a distance across the surface, rarely reaching the anterior border. Occasionally such a fissure starts from the anterior border and rarely there is such a fissure connecting with neither border.

Fig. 1067.—Portion of Section of the Spleen of an Adult Man. × 15. (Lewis and Stöhr.)



Structure.—The peritoneal covering of the spleen, **tunica serosa,** is intimately bound to the underlying, whitish, highly elastic fibrous capsule, the **tunica albuginea** (fig. 1067). This is composed mainly of white fibrous connective tissue but contains numerous fine elastic fibers, and a few smooth muscle fibres. It is much thicker than the serous covering and completely invests the spleen. From its deep surface the tunica albuginea gives off into the interior numerous trabeculæ, **trabeculæ lienis,** which join with one another and form a framework in which course the blood-vessels, more especially the veins. It is through the contraction of the smooth muscle fibres in the tunica albuginea and trabeculæ, that the regular periodic contraction and expansion of the spleen is produced.

In the meshes of the trabecular network, lymphoid tissue which forms the proper splenic tissue, the **pulpa lienis,** is located. This is soft, friable, and dark brownish or bluish-red in colour. In this, in a fresh spleen, are seen small round whitish or greyish masses from .25 to 1.5 mm. in diameter, the **Malpighian corpuscles** [noduli lymphatici lienales; Malpighii].

The trabeculæ are in connection with a reticular network which permeates the spleen substance or spleen-pulp. Mall has shown that the trabeculæ and vascular system together outline masses of spleen-pulp about 1 mm. in diameter, known as **splenic lobules.** Each lobule is bounded by three main trabeculæ, from each of which secondary trabeculæ pass into the substance of the lobule incompletely subdividing it into compartments, filled with splenic pulp, arranged in the form of anastomosing columns or cords and designated as pulp-cords. The branches of the splenic artery, after coursing for a short distance in the main trabeculæ, leave these, and, after further division, become surrounded with a layer of adenoid tissue, which layer presents here and there irregular thickenings forming the Malpighian corpuscles. An arterial branch, surrounded with adenoid tissue, enters the apex of a splenic lobule, constituting its intralobular vessel, which, soon after entering the lobule, loses its adenoid sheath and then sends a branch to each of the above-mentioned compartments. These branches do not anastomose. They give off terminal branches which course in the pulp-cords, form dilations, **ampullæ,** and terminate directly or indirectly in the large venous spaces found between the pulp-cords. From the latter the blood passes, by means of small intralobular veins, to interlobular veins situated in the trabeculæ bounding the lobules. Some of the ampullæ are connected with one another by capillary branches.

Blood-supply.—The spleen receives its blood from the splenic artery, which is very large in proportion to the size of the organ it supplies. It divides in the phrenicolienal ligament into from three to six or eight branches, **rami lienales** (fig. 1062), which enter the spleen at the hilus. After entering the spleen the arteries divide and subdivide and run to their termination in the ampullæ without anastomosing. They form what are known as terminal arteries. The main splenic artery is very tortuous. The vein, **vena lienalis,** leaves the spleen usually by the same number of branches as the entering artery. These unite in the phrenicolienal ligament to form a large trunk which is straighter than the splenic artery and lies caudal to it.

The lymphatics.—A superficial and a deep set of lymphatics have been described in the spleen. The former is said to form a plexus beneath the peritoneum and the latter to be derived from the fine perivascular spaces in the adenoid tissue around the vessels. From these several trunks arise and joining at the hilus pass between the layers of the phrenicolienal ligament to empty into the lymph-glands dorsal to and around the cephalic border of the tail of the pancreas. The presence of both superficial and deep sets of lymphatics in the human spleen has been denied by some investigators. According to Mall, there is no deep set.

The nerves.—The nerves are derived from the right vagus and from the cœliac plexus. They enter the spleen at the hilus, accompanying the branches of the lienal artery. They are composed mostly of non-medullated fibres which form a rich plexus around the arteries supplying the muscular fibres in the media while a second group has been traced to the muscular fibres of the trabeculæ.

Development of the spleen.—The first anlage of the spleen is seen in the fifth week of fœtal life as a swelling on the dorsal (left) surface of the mesogastrium. This is due to an increase in the mesenchymal cells as well as to a thickening of the cœlomic epithelium. This latter becomes stratified, and indistinctly differentiated from the underlying embryonic connective tissue through the transformation of the deepest of the epithelial cells into mesenchymal cells. As development proceeds the thickened mass becomes entirely isolated and the cœlomic epithelium covers it as a single layer.

The arteries are seen first as a capillary network throughout the organ which considerably later become arranged as tufts of widened capillaries, the anlage of the vascular structural unit. These spherical groups of arterial capillaries leading by wide openings into a wide meshed venous plexus are bounded by trabeculæ from the capsule. The number of structural units in the spleen seems to be fixed fairly early but the size and complexity changes greatly. The spherical mass with a single central artery changes to the adult condition where the central artery gives off side branches, each of which has a spherical mass of capillaries, and the pulp intervenes between the artery and the vein so that the capillary circulation of the early embryo becomes the cavernous circulation of the adult. The lienal lymphatic nodules of Malpighi and the splenic pulp appear only in the latter half of embryonic life.

THYREOID GLAND

The **thyreoid gland** [glandula thyreoidea] is an extremely vascular, ductless gland, whose internal secretion, acting as a stimulus to the tissues, has a profound influence on the nutrition of the body and on the nervous system. It is a single organ composed of two lateral, frequently unsymmetrical, masses, joined together by a transverse median band. The median transverse band or *isthmus* [isthmus gl. thyreoideæ] is thin and narrow, and often has a long slender process, the *pyramidal lobe* [lobus pyramidalis], extending from it cephalically. The lateral parts or *lobes* [lobi, dexter et sinister] form the principal mass of the gland.

It is **situated** in the ventral portion of the middle third of the neck on both sides of the larynx and the cephalic end of the trachea, dorsal to the infrahyoid group of muscles.

The **consistency** of the thyreoid gland is uniformly soft and compressible. The **colour** is reddish, with a brownish or yellowish cast, but becoming more bluish or reddish with changes in its blood content.

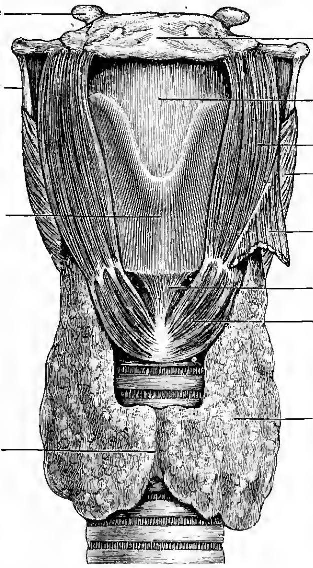
The **size** is subject to considerable individual variation and is slightly greater in women than in men. The normal thyreoid gland measures from 4 to 6 cm. in width at its widest part. The lateral lobes measure from 5 to 8 cm. in length, about 2 cm. in width, and from 1.5 to 2.5 cm. in thickness. The right is usually a little longer than the left. The isthmus averages from .6 to .8 cm. in thickness and from .5 to 1.5 cm. in height.

The **weight** of the normal gland averages about 30 grams; but many specimens are found as light as 20 grams, and others weigh as much as 60 grams.

When hyperemic or congested the size of the gland may be markedly augumented. This occurs normally in most women at puberty and during menstruation and pregnancy. In various abnormal conditions of the gland there is an increase in size, sometimes to a marked degree. These enlargements are ordinarily grouped under the term struma or **goitre**, and may be associated with either a hyper- or hyposecretion of the gland. Decrease in size is common in old age and may appear prematurely in certain diseases.

The **shape** of the gland as viewed from the ventral surface is that of a capital **U** with the concavity directed cephalically (fig. 1068). The sides of the **U** are formed of the more or less elongated lobes connected slightly cephalic to their

Fig. 1068.—Ventral View of the Thyreoid Gland.



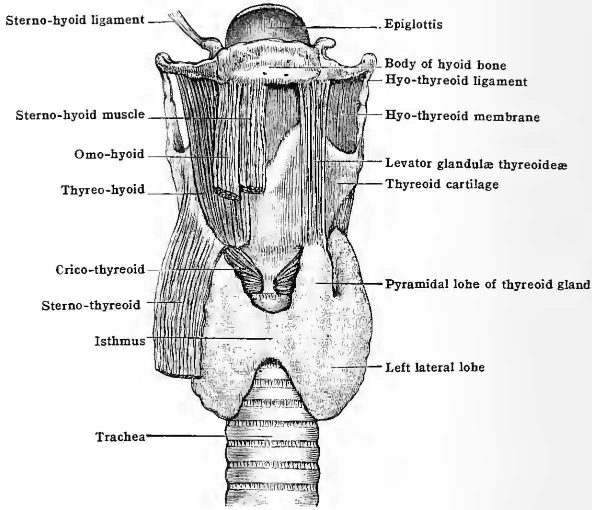
thickened caudal ends by the thin transverse isthmus. In transverse sections through the isthmus the gland is also **U**-shaped with the concavity directed dorsally, the lobes being on each side and the isthmus ventral to the trachea (fig. 1068). The surface of the gland is somewhat unevenly roughened.

The **isthmus glandulæ thyreoidæ** usually becomes wider laterally where it is attached by its two extremities to the lateral lobes (figs. 1068, 1069). Its ventral surface which is flat or somewhat convex is covered superficially by the subcutaneous tela and skin and beneath these by the superficial and middle layers of the cervical fascia. Between the layers of cervical fascia and close to the median line is the sterno-hyoid muscle and more laterally and deeper the sterno-thyreoid muscle. The dorsal surface is concave and is in relation with the first two to four rings of the trachea and sometimes with the cricoid cartilage.

The size and form of the isthmus is subject to considerable variation. It may be very short. Rarely it is wanting entirely or connects with but one lateral lobe. Its superior border is, as a rule, concave and is connected in many cases with the pyramidal lobe. The caudal border, although usually on the third ring of the trachea and 2.5 to 3 cm. from the jugular notch of the sternum, may be especially developed so that it extends caudally beyond the lateral lobes and produces a process which is known as the **medial lobe**.

The **pyramidal lobe** is usually a narrow elongated flattened somewhat conical process of thyreoid tissue representing the persistent portion of the median embryonic thyreoid (fig. 1069). Its base is attached ordinarily to the left side of the

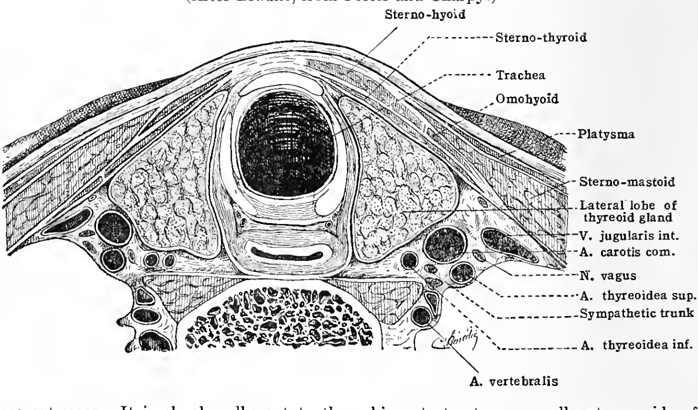
Fig. 1069.—Thyreoid Gland, with Pyramidal Lobe and Levator Muscle.



superior border of the isthmus and its apex which extends cephalically a variable distance, often to the superior border of the thyreoid cartilage, is attached by a fibrous cord, the **thyreoid ligament.**

The pyramidal lobe is not always present. Some investigators have found it present in only 40 per cent of all cases; others in as high as 90 per cent. The average is somewhere between

Fig. 1070.—Cross-section of Neck Showing Relations of the Thyreoid Gland. (After Braune, from Porier and Charpy.)



these extremes. It is closely adherent to the subjacent structures, usually at one side of the median line, more often the left. The superficial relations of the pyramidal lobe are similar to those of the isthmus. Its deep surface is in relation also with the cricoid and thyreoid cartilages, the crico-thyreoid muscle and the hyo-thyreoid ligament.

The pyramidal lobe, though usually single, may be double or bifid at its caudal end, one process joining each lateral lobe. It may be attached in the angle between the isthmus and one of the lateral lobes, or to the lateral lobe itself. It may be cylindrical, band-like, or swollen at its centre or cephalic end and is occasionally entirely separate from the rest of the thyreoid or divided into separate detached parts, thus forming accessory thyreoids. The apex in some cases extends to the middle of the thyreohyoid membrane or rarely to or beyond the hyoid bone or the process may be quite short. In the thyreoid ligament, attached to the apex, muscle fibres are sometimes found, aberrant parts of the infrahyoid muscles, the **levator of the thyreoid gland.**

The thyreoid **lobes**, right and left, are placed on each side of the trachea and larynx (figs. 1068, 1069, 1070). Each lobe is somewhat pyramidal in shape and presents for examination a base, an apex, a medial, a ventro-lateral, and a dorsal surface.

The **base** is roughly convex or pointed, rarely flattened, usually at the level of the fifth or sixth ring of the trachea (figs. 1068, 1069).

It is separated from the jugular notch of the sternum by a distance of 1.5 to 2 cm. but when the head is extended the distance is greatly increased. It is in relation with the inferior thyreoid artery and numerous veins, mostly tributaries of the inferior thyreoid vein.

The **apex** is pointed or rounded (figs. 1068, 1069). It is directed cephalodorsally and is situated at the dorsal border of the lateral lamina of the thyreoid cartilage at the level of its caudal, or rarely its middle, third.

It is covered by the sterno-thyreoid muscle beneath which the superior thyreoid artery accompanied by the corresponding vein crosses the apex to reach the gland. It is also crossed in this situation by the external ramus of the superior laryngeal nerve as it passes to the crico-thyreoid muscle.

The **medial surface** of the lateral lobe is concave and intimately bound to the trachea and cricoid cartilage (fig. 1070). Toward the apex it becomes more flattened where it comes into contact with the lateral lamina of the thyreoid cartilage.

At the border where this surface joins with the dorsal surface it is in relation with the œsophagus and pharynx, and in the angle between these structures and the trachea and larynx it is close to the recurrent laryngeal nerve.

The **dorsal surface** (fig. 1070) is broad and rounded caudally, but toward the apex is reduced to a mere border. It lies upon the fascial sheath containing the common carotid artery, the jugular vein, and vagus nerve, most intimately related to the common carotid artery which usually produces a groove in it.

The inferior thyreoid artery sends large branches over this surface. The inferior thyreoid veins also have large branches here. Imbedded in the connective tissue in relation with this surface the *parathyreoid bodies* are found, and in some cases the recurrent nerves are placed so far laterally that they also touch this surface. In many cases the sympathetic trunk and the middle cervical ganglia of the sympathetic with the cardiac branches are closely related to the dorsal surface of the gland.

The **ventro-lateral surface** is convex and is separated by loose connective tissue from the overlapping sterno-thyreoid, sterno-hyoid, and omo-hyoid muscles.

More superficial on its lateral aspect is the sterno-cleido-mastoid muscle. The above muscles are enclosed by the superficial and middle sheets of the cervical fascia. In the subcutaneous tela the platysma muscle spreads over the gland. This surface of the gland is covered by a plexus of veins and by branches of the superior thyreoid artery.

Accessory thyreoid glands are small masses of glandular tissue one or more of which may be found situated in the median line or at one side of it anywhere between the isthmus and the root of the tongue. They vary considerably in size and represent parts of the pyramidal lobe or isthmus which have become completely separated from the rest of the gland. In structure they are composed of the same tissue as the rest of the gland.

Fixation.—In addition to the connective tissue which binds the thyreoid gland to the trachea, it is attached by the connection of its capsule with the cervical fascia and by the fibrous prolongations from the capsule.

These prolongations are found medially attaching the isthmus and adjoining portions of the lateral lobes to the ventral surface of the cricoid cartilage, the caudal border of the thyreoid cartilage, and the sheath of the crico-thyreoid muscles, and laterally attaching the lateral lobes to the trachea and lateral surface of the cricoid cartilage. In addition to these the connection of the vessels and nerves to the gland helps to fix it in position.

Structure.—The thyreoid gland like other glands is composed of a connective-tissue **stroma** supporting an epithelial secreting **parenchyma**.

The connective tissue which covers the surface of the gland forming for it a **capsule,** may be divided into two layers, superficial and deep.

The *superficial layer* intimately connected with and derived from the fascia colli as pointed out above has an important function in supporting and fixing the gland. This layer is in some cases thin and transparent; in other cases it is very tough and thick. It is connected by loose areolar tissue with the thin deep layer of the capsule. Between these two layers the larger vessels run for a space before entering the gland and the veins, particularly, form here considerable plexuses.

From the deeper layer of the capsule numerous trabeculæ and septa carrying blood-vessels, lymphatics, and nerves pass into the gland and imperfectly separate its parenchyma into irregular masses of variable size, the **lobules** [lobuli]. Each lobule is composed of a number of closed, non-communicating, irregular, spherical, ovoid, or sometimes branched alveoli, acini or **vesicles,** varying in size from .045 to .22 mm. in diameter and separated and bound together by a vascular connective tissue continuous with that surrounding the lobules and with that of the cap-

Fig. 1071.—Arteries of the Thyreoid Gland, Anterior View. 1. (Testut and Jacob.)

sule. The vesicles are filled with a yellowish viscous fluid, known as **colloid,** the secretion of the epithelial cells.

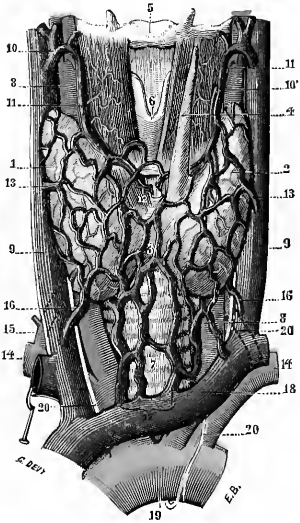
The vesicles are lined with a single layer of epithelial cells of a fairly uniform cuboidal or columnar shape, becoming flattened in distended vesicles and in old age. The cells are not supported by a basement membrane but are in close relation with connective tissue and capillary blood-vessels. An extremely rich lymphatic network surrounds the vesicles and the lymph-vessels come into intimate relation with the cells. Through these vessels the secretion is conveyed from the gland to the general circulation.

Blood-vessels.—The thyreoid gland has an extremely abundant blood-supply. The arteries are usually four in number but occasionally five (figs. 1071–1073).

The **superior thyreoid arteries** divide into two, three, or more main branches which reach the gland near the apex of the lateral lobes and supply mainly the ventral and medial surfaces of the cephalic portion of the lobes (fig. 1071). There is usually also a dorsal branch, which anastomoses with a branch from the inferior thyreoid. One of the ventral branches frequently connects along the cephalic border of the isthmus with its fellow of the opposite side. The **inferior thyreoid arteries** break up into two or three main branches, occasionally into many fine twigs, which reach the dorsal surface of the lateral lobes near the caudolateral borders and supply mainly the dorsal and lateral surfaces of the caudal part of the gland (fig. 1071). There is usually a well-marked branch which passes cephalically to anastomose with a good-sized branch from the superior thyreoid. Small branches are distributed to the ventral surface of the caudal portion of the lobes and isthmus. The small fifth artery, the **thyreoid ima artery,** occasionally present, ascends on the ventral surface of the trachea and reaches the gland at the caudal border of the isthmus or of either lobe. It anastomoses with the other arteries which may be correspondingly reduced in size. The above-mentioned arteries branch freely and are distributed over the surface of the gland between the two layers of the capsule where they anastomose extensively with one another and with the arteries of the opposite side. From the surface plexus branches pass with the septa and trabeculæ through the gland to break up into the capillary plexuses around the vesicles.

The relation of the inferior thyreoid artery to the recurrent nerve is important from a surgical point of view but unfortunately is not constant. In some cases the nerve is ventral to the artery, more often on the right, in other cases it is dorsal and often the nerve passes between the branches of the artery. Their relation is most intimate close to the trachea Fig. 1073.

FIG. 1072.—VESSELS OF THE THYREOID GLAND, ANTERIOR VIEW. 1, 2, 3, Lateral lobes and isthmus; 4, pyramidal lobe; 5, hyoid bone; 6, thyreoid cartilage; 7, trachea; 8, common carotid; 9, internal jugular; 10, thyreo-linguo-facial vein; 11, superior thyreoid artery; 12, inferior laryngeal vessels; 13, middle thyreoid vein; 14, subclavian artery; 15, inferior thyreoid artery; 16, inferior lateral thyreoid veins; 17, inferior medial thyreoid veins; 18, left innominate vein; 19, aortic arch; 20, vagus nerve. (Testut.)



The **veins** (fig. 1072) issue from the substance of the gland along the septa which penetrate from its capsule. Between the two layers of the capsule they form a rich plexus of large vessels from which three large branches issue on each side.

The **superior thyreoid veins** leave the capsule of the ventral surfaces of the lateral lobes near their apices and pass cephalo-laterally to empty into the internal jugular veins, sometimes with the facial veins. The **middle thyreoid veins** are sometimes absent, when present they are often very small and pass from the lateral border of the lateral lobes laterally to empty into the internal jugular vein. The **inferior thyreoid veins** arise from the caudal and lateral part of the dorsal surfaces of the lateral lobes and pass caudolaterally to open into the innominate veins. Ventral to the trachea, caudal to the isthmus, the two inferior thyreoid veins are connected by numerous cross anastomoses and occasionally they open by a single trunk which joins the left innominate vein. A thyreoidea ima vein is sometimes present.

The **lymphatics** of the thyreoid gland begin as abundant plexuses around the vesicles of the gland lobules. These connect with the interlobular branches which empty into radicles accompanying the blood-vessels through the septa to the surface of the gland where they join a considerable plexus placed between the two layers of the capsule. From the cephalic portion of the isthmus and lobes efferent vessels extend cephalo-medially to one or two small pre-laryngeal glands and cephalo-laterally along with the superior thyreoid artery to the deep cervical glands. From the caudal part of the lateral lobes and isthmus efferent vessels pass caudally to some small pre-tracheal glands and caudolaterally to the deep cervical glands.

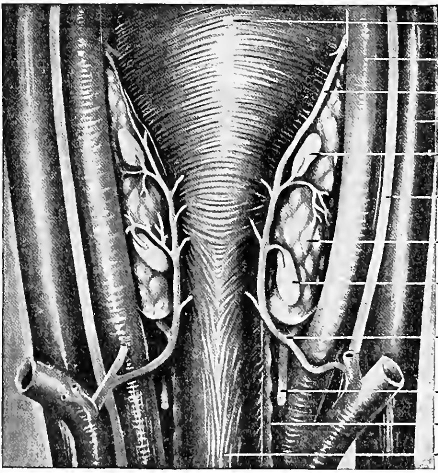
The **nerves** of the thyreoid gland are probably all derived from the sympathetic and arise from the middle and inferior cervical ganglia and accompany the arteries to the gland.

Development.—The thyreoid gland is first seen in very young embryos as a prominence on the ventral wall of the pharynx. This becomes a stalked vesicle and divides into lateral lobes. The stalk elongates forming the **thyreoglossal duct** of His. Later the lumen is obliterated and the duct is then represented by an epithelial cord which soon loses its connection with the pharynx. It opens at first cephalic to the regular second branchial arch on the summit of the tuberculum impar but later shifts to its caudal boundary (Grosser). It is represented in the adult only by a short blind pouch, the **foramen cæcum** but very rarely a considerable duct may be present. The bilobed mass appears to shift caudally, increasing in size and spreading laterally and dorsally. The median cord of cells formed from the stalk becomes the isthmus and the pyramidal lobe, when this is present, the lateral portions form the lateral lobes. The gland is now composed of irregular, in general transversely disposed cords of cells. More rapid growth later occurs in the centres of the lateral lobes and the cell cords become closely packed with little connective tissue between. Lumina appear in different places in the cell cords and the cell cords are broken up into groups of cells; in these the lumina continue to appear even up into early childhood. On each side, diverticula from the more caudal pharyngeal pouches, the **ultimobranchial bodies,** come into contact with the dorsal and lateral parts of the anlage of the thyreoid gland and become partly enclosed in the neighbourhood of the transversely running cell cords. This core of cells becomes either a compact body or an irregular group of cells and is probably not transformed into thyreoid tissue.

THE PARATHYREOID GLANDS

The **parathyreoid glands** are small masses of epithelial cells found in the neighbourhood of the dorsal surface of the thyreoid gland but quite distinct from it and

Fig. 1073.—Parathyreoid Glands, Viewed From Behind (Natural Size).



of different structure. They are ductless glands and although very small they are essential to life.

The usual **number** is four, two on each side, in relation with the lateral lobes of the thyreoid gland (fig. 1073). In **colour** they are yellowish with more or less of a reddish or brownish tint but lighter than the thyreoid gland. Their **consistency** varies somewhat but usually it is softer than that of the thyreoid gland. The **shape** of the majority of the glands is a flattened ovoid, sometimes tapering at one or both ends, rarely a flattened circular disc. At some place on the surface there is usually a depressed hilum where the artery enters and the vein leaves. The average **size** of the glands is 6 to 7 mm. in length; 3 to 4 mm. in width and 1 to 2 mm. in thickness. Occasionally they may be found 15 mm. in length. They weigh from .01 to .1 gm. with an average of .035 gm. From their situation they have been divided into a *superior*, or internal, derived from the fourth branchial pouch, and an *inferior*, or external, derived from the third branchial pouch.

The **superior parathyreoid glands** (fig. 1073) are found, as a rule, on the dorsal surfaces of the lateral lobes of the thyreoid gland at about the junction of the cephalic and middle thirds Occasionally they may be situated in the areolar tissue at the level of the apex of the thyreoid gland or cephalic to it. They may be ventral to the prevertebral layer of the cervical fascia, on the dorsal wall of the œsophagus or pharynx and close to the dorsomedial margin of the thyreoid gland. They may also be placed at the level of the caudal border of the cricoid cartilagel rarely as high as the inferior cornu of the thyreoid cartilage or as low as the sixth trachea, ring. Sometimes they are imbedded completely in the thyreoid gland. As a rule, they are tightly attached to the capsule of the thyreoid gland or situated between its layers.

The **inferior parathyreoid glands** (fig. 1073) are less constant in their situation than the superior. They usually are found in relation with the dorsal surface of the lateral lobes of the thyreoid glands, not far from their bases. They may be quite outside the region of the thyreoid gland along the carotid arteries or the sides of the trachea, or they may be placed more cephalically than usual or extend caudal to the gland as far as the tenth tracheal ring, even into the thorax. They are imbedded, when caudally placed, in fatty areolar tissue in relation with the apex of the thymus gland and the inferior thyreoid veins or applied against the œsophagus.

The parathyreoids are intimately related to branches of the inferior thyreoid artery, a separate branch of which supplies each of them. When there is a large branch of the inferior thyreoid artery anastomosing with the superior they are more or less in line with this.

Each parathyreoid gland is surrounded by a fibrous *capsule* from which extremely vascular septa and trabeculæ penetrate into the gland separating and binding together the masses of polyhedral cells which are arranged in solid groups or intercommunicating cords of varying sizes and shapes.

The cell cords, as a rule, are not arranged like the thyreoid vesicles. At times the secretion may accumulate and produce a vesicular appearance and the secretion then closely resembles colloid. Two kinds of cells, oxyphile and principal cells, have been described; but the intermediate forms suggest that these are the same sort of cells in different stages of functional activity. The blood-vessels are distributed in the connective tissue of the trabeculæ and thus their sinusoids are brought into close connection with the cells of the gland. The nerves are also distributed along the septa. In the highly vascular connective tissue between the cell cords fat cells are found separate or in groups.

The *number* of parathyreoid glands found by different investigators varies. The average number in a series of cases is less than four. Whether this is due to a real absence of the glands or to failure to find them due to their aberrant location, their inclusion in the thyreoid gland, or the fusion of two glands, is not clear. In some cases it is the superior glands, in other cases the inferior glands, which appear to be missing. On the other hand various competent observers have reported finding more than four parathyreoid glands. Five or six are occasionally found; as many as eight have been recorded in one instance. In these cases the number on a side may not be symmetrical. The increased number may be due to the separation of buds in the course of development. The parathyreoid glands are liable to be associated with accessory thymus masses, with small lymphatic glands, and with fat lobules; and as they may somewhat resemble each of these, they may be mistaken unless a microscopic examination is made.

Blood-supply.—Each parathyreoid gland is supplied by a single separate artery derived, as a rule, from one of the glandular, muscular, or œsophageal branches of the inferior thyreoid artery or from the anastomosing branch between the superior and inferior thyreoid arteries. When the glands are in aberrant positions their arteries may be derived from the nearest source. The arteries are distributed along the trabeculæ and septa. The veins returning the blood either follow the arteries or they pass to the surface of the gland where they break up into a plexus of thin-walled vessels. Upon leaving the gland the veins empty into some one of the branches of the thyreoid veins.

Development.—The parathyreoids (epithelial bodies) begin as proliferations of the epithelium on the oral and lateral walls of the dorsal diverticulum of the third and fourth pharyngeal pouches. The cells show early a histological differentiation with vacuolated and reticulated plasma. The common pharyngo-branchial ducts diminish in size and become constricted off and separated from the pharynx. The parathyreoid glands later become independent and separated from the thymus anlages. The epithelial cells grow out in the form of cords separated by connective tissue and in intimate relation to the blood-vessels. Different kinds of cells are not distinguishable until postfœtal life when evidence of secretion begins.

THYMUS

The **thymus** is a transitory organ of epithelial origin, but in structure resembling the lymphoid tissue. Its function is not clearly understood but it seems to be intimately associated with the growth and nutrition of the individual, and it is classed with the ductless glands of internal secretion.

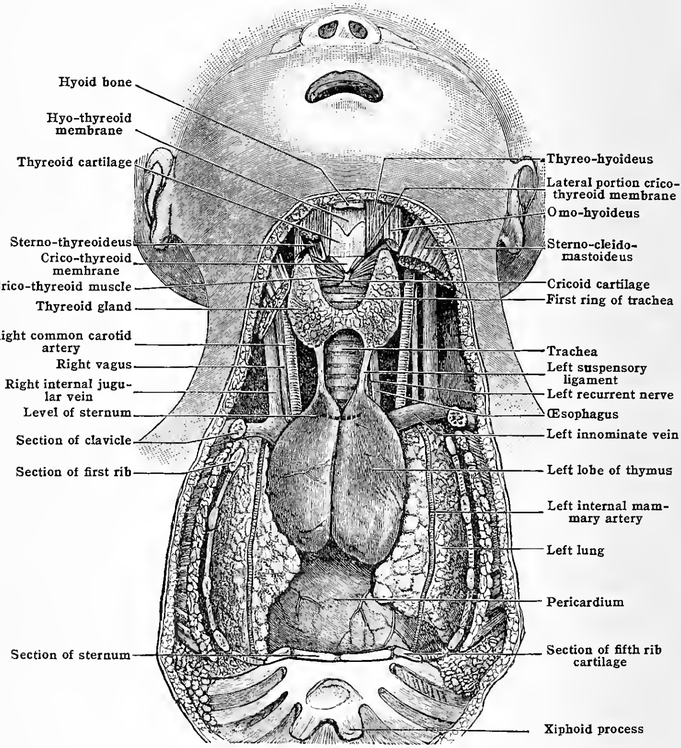
It is **situated** in the ventro-cephalic part of the thorax and extends into the caudal part of the neck (fig. 1074). It lies between the two pleural sacs ventral to the heart and great vessels, dorsal to the sternum and the sterno-thyreoid and sterno-cleido-mastoid muscles.

Although arising from the branchial clefts one on each side of the neck, the two portions become so closely associated that they are usually spoken of as one. Each of these parts is ordinarily regarded as a **lobe of the thymus** [lobus, dexter et sinister].

In **colour** the thymus is pinkish or reddish grey in the fœtus and newborn, becoming greyish white in the adult or yellowish as it undergoes involution. It is composed of soft, yielding tissue more friable than the thyreoid or spleen.

In **size** the thymus varies greatly. Under normal conditions it appears to attain its maximum size at about the age of puberty, and to continue large as long as the body continues to grow and then to undergo a gradual involution.

Fig. 1074.—Thymus Gland in a Child at Birth.



It is, however, very sensitive to any nutritive changes of the individual and becomes very small, even in the infant, under the influence of wasting diseases. It not infrequently exists in the adult only as a vestige but in some cases it may remain large until middle age or later. At birth it is usually from 50 to 60 mm. long cephalo-caudally and about half as broad.

The **weight** varies with the size. It is given by Hammar as over 13 gm. at birth, increasing to double this between the sixth and the tenth years and gaining its maximum of between 37 and 38 gm. between the eleventh and fifteenth years. From this time the weight decreases until between the ages of fifty-six and sixty-five it weighs between 25 and 26 gm. and at seventy-five years may be as light as 6 gm. The involution of the gland is not accompanied by a corresponding reduction in size and weight as the thymic tissue is gradually invaded by fatty tissue which maintains to some extent the form of the organ.

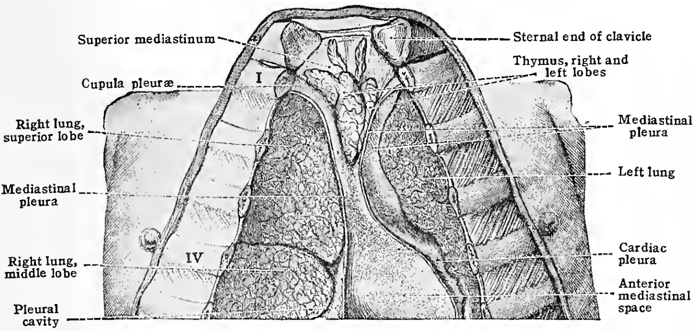
In **shape** the thymus is an elongated, spindle-shaped mass consisting of the central portion or body and two extremities (figs. 1074, 1075). The **body** is the widest and largest part of the organ and has no distinct separation from the extremities. The **inferior extremity** is also broad and is known as the base. It rests on the pericardium, ordinarily extending as far caudal at birth as the atrio-ventricular furrow but rarely it may extend as far as the diaphragm. The **superior extremity** is much elongated and extends into the neck. It is represented by two horns nearly always unequal in size the left being usually the larger. It extends nearly to the thyreoid gland, in some cases reaching it.

Relations.—Topographically the thymus when well developed is divided into cervical and thoracic parts.

The **cervical portion** presents for examination an anterior surface and a posterior surface. The **anterior surface** is convex and is in relation with the sterno-thyreoid and sterno-cleido-mastoid muscle. The **posterior surface** is concave and rests medially upon the anterior surface of the trachea, laterally upon the common carotid artery and sometimes on the left side upon the œsophagus.

The **thoracic portion** of the thymus is much more important representing four-fifths of the organ (fig. 1075). It presents for examination an anterior, a posterior, and two lateral surfaces. The **anterior surface** is dorsal to the sternum from which it is separated cephalically by the origin of the sterno-thyreoid muscle. To a less extent it is in relation with the sterno-clavicular articulation and comes into contact laterally with three or four of the cephalic sterno-costal articulations and lateral to this with the internal mammary artery. The **posterior surface** is largely concave and is in relation caudally with the pericardium which separates it from the

Fig. 1075.—Thymus in an Adult. $\times\frac{1}{3}$. (From Toldt's Atlas.)



right atrium and ventricular portion of the aorta and pulmonary artery. The middle part is in relation with the aorta and to the right of this with the superior vena cava. The cephalic part is in relation with the branches of the aorta and superior vena cava. The lateral **surfaces** are somewhat flattened and are separated from the lungs by the mediastinal pleura. The phrenic nerve on the right side runs in the pleura near the dorsal border of this surface, on the left it is, as a rule, not in direct contact with the thymus.

Structure.—The two lateral lobes of which the thymus is composed are rarely of the same size; the right is usually the more strongly developed. They are joined at an oblique plane so that the ventral surface of the right is narrow and its dorsal surface broader and the reverse condition is found in the left lobe. The two lobes are separated from one another by connective tissue. Rarely the two are joined by a medial portion, **isthmus**, near the middle or toward the caudal end (fig. 1076).

Each lobe of the thymus is completely surrounded by a thin delicate connective-tissue capsule from which numerous septa extend through the gland accompanied by the blood-vessels and nerves. The capsule is composed mainly of white fibrous connective tissue with some elastic fibres. It rarely contains much fat in the newborn but the amount of fat increases as development and involution proceed. Fibrous prolongations from the capsule may extend from the apices of the lobes to be attached to the cervical fascia in the region of the lateral lobes of the thyreoid gland, acting as suspensory ligaments for the gland.

The lobes of thymus are divided into numerous small **lobules** [lobuli thymi] 4 to 11 mm. in diameter. These are of roundish or polyhedral shape with bases toward the surface where they show as polygonal areas. The lobules are separated and also bound together by the loose fibrous tissue septa which extend from the capsule.

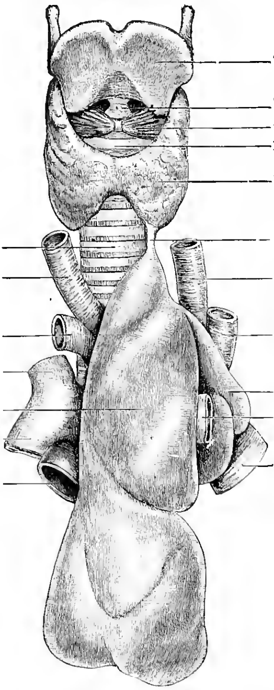
Each of the primary lobules of the thymus is divided into a number of secondary lobules or follicles 1 to 2 mm. in diameter. These lymphoid-like masses of tissue are composed of a reticulum containing in its meshes lymphocytes or **thymus corpuscles**. The tissue is denser near the surface, forming a **cortex** and passes gradually into a tissue with looser meshed reticulum near the centre, **medulla**. In the medulla there are nests of concentrically arranged degenerated epithelial cells enclosing a central mass of granular cells containing colloid. These nests are termed the **concentric corpuscles of Hassall.** The cortex is subdivided by secondary connective-tissue septa extending in from the septa between the lobules.

The **arteries** of the thymus are somewhat varied in their origin, usually derived from the internal mammary and inferior thyreoid of each side; branches are sometimes received from the innominate, subclavian, and superior thyreoid arteries. They reach the gland in various places and spreading out in the capsule pass with the trabeculæ through the gland to form a plexus around each small lobule. From this capillaries pass through the cortex to the medulla. The veins issue from the thymus in various places and are seen as numerous branches on its surface. The efferent vessels drain into various veins, mostly into the left innominate vein, also smaller branches into the internal mammary and inferior thyreoid veins.

The **lymphatics** arise around the small lobules and pass through the interlobular septa to the surface from which they are drained into small lymph nodes near the cephalic extremity, into glands ventrally between the thymus and the sternum, and into other glands dorsally between the thymus and the pericardium.

The **nerves** of the thymus are very minute. They are derived from the cervical sympathetic and from the vagus and reach the thymus for the most part along with the blood-vessels which they accompany through the septa.

Fig. 1076.—Thymus in a Child of Two Years.



Development.—The thymus arises from the endodermal portion of the third pharyngeal pouch on each side, as a thickening due to an increase in the epithelial cells, followed by the production of a diverticulum. At about the sixth week the connections of the pouches with the branchial clefts are cut off but a strand of tissue may persist to represent the stalk. These thick-walled cylinders become solid cords, elongate so as to extend caudally into the thorax, and enlarge by a series of secondary buddings. The glands of the two sides come into contact and become intimately associated. The cephalic portion, as a rule, later atrophies and disappears. Occasionally a small part of it remains near the thyreoid cut off from the rest of the gland as an accessory thymus. From the fourth pharyngeal pouch rarely a thymus bud may be developed which produces in the adult also an accessory thymus. The epithelial character of the cells remains plainly evident for a time, then the characteristic differentiation into lymphoid structure, cortex and medulla appears. The reticulum and concentric corpuscles are undoubtedly of epithelial origin; but the thymus lymphocytes are considered by Hammar and others as leucocytes which have migrated to the thymus, while they are regarded by

Stöhr and his followers as modified epithelial elements, not true blood cells. Maurer, Bruant, and Bell regard them as modified epithelial cells which become true functional leucocytes.

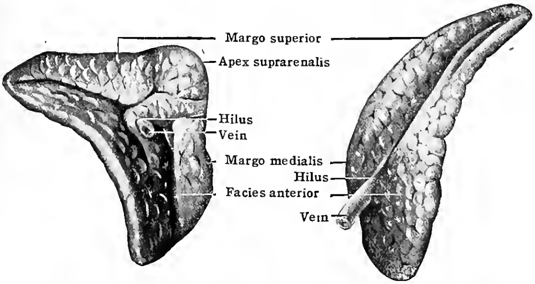
THE CHROMAFFIN SYSTEM

It has recently been shown that in connection with the ganglia of the sympathetic nervous system, special cells, other than the nerve cells, are found. These differ from the nerve cells in that when subjected to the action of chromic acid salts there can be demonstrated in their protoplasm small granules which take on a darker stain. These cells are therefore known as **chromaffin cells.** They, with the cells of the sympathetic system, are derived from the ectoderm. They appear first as indifferent cells, the sympatho-chromaffin cells. Some of these later develop into sympathetic ganglion cells, others into chromaffin cells. Some of these latter cells remain, isolated or in groups, permanently associated with the sympathetic ganglia, the **paraganglia;** others become separated and form the medullary portion of the suprarenal glands, the aortic paraganglia, and the glomus caroticum.

THE SUPRARENAL GLANDS

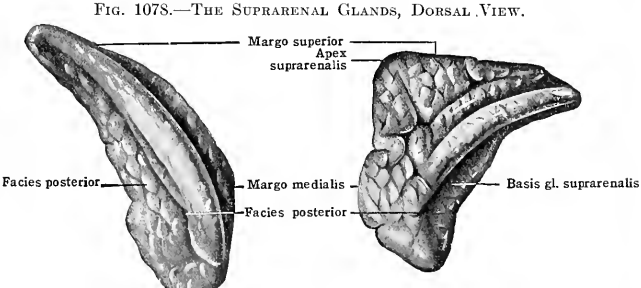
The **suprarenal glands** [glandulæ suprarenales] or adrenal glands are small irregularly shaped glandular bodies composed of two quite different organs. In the lower vertebrates these two parts are entirely separated from one another

Fig. 1077.—The Suprarenal Glands, Ventral View.



but in man and the mammals they have become joined together one within the other. The external cortical portion, of unknown function, is developed from the mesoderm. The internal medullary portion is derived from the sympatho-

Fig. 1078.—The Suprarenal Glands, Dorsal View.



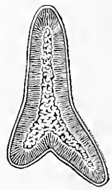
chromaffin tissues and thus from the ectoderm in common with the sympathetic nervous system. This part of the suprarenal glands is known to produce an internal secretion which reaches the general circulation through the veins and whose principal function seems to be to aid in keeping up the tone and activity of the muscle and other tissues innervated by the sympathetic system.

Situation.—The glands are deeply placed in the epigastric region (fig. 1080) lying in the dorsal and cephalic part of the abdominal cavity, one on either side of the vertebral column in variable relation with the upper extremity of the kidney of the corresponding side.

Rarely they retain the fœtal relation, capping the superior extremity of the kidney and extending a little upon both medial and lateral borders. More frequently (especially on the left) they are placed more upon the medial borders of the kidneys, extending (on the left) as far caudal as the hilus, sometimes coming in contact with the renal vessels. An intermediate position is often found, especially on the right. In the high positions the suprarenals may be on a level with the tenth intercostal space or eleventh rib. In the low positions they may extend as far caudally as the first lumbar vertebra. The left is usually, but not always, a little higher than the right, corresponding to the position of the kidneys.

Fixation.—The suprarenals, enclosed in the renal adipose capsules, are attached to the renal fascia by connective-tissue strands and are loosely bound by connective tissue to the kidneys. The attachment to the kidneys is, however, so loose that the suprarenals are not dislocated when the kidneys are displaced. In addition to the attachments common to them and to the kidneys, they are joined by connective-tissue bands to the diaphragm, vena cava, and liver on the right side and to the diaphragm, aorta, pancreas and spleen on the left. They have also additional means of fixation through the arteries, veins, and nerve fibres which enter and leave them, and through the parietal peritoneum which in places covers their ventral surfaces.

Fig. 1079.—Diagrammatic Section of the Suprarenal Gland.



Size and weight.—The size of the suprarenals is subject to considerable variation within physiological limits, in some cases being relatively twice as large as in others. The two glands are rarely of the same size, the right being more often the smaller.

Proportionately they are much larger in the fœtus and embryo than in the adult, but they do not decrease in size in old age. They appear to be slightly lighter in women than in men. The average weight in the adult is from 4 to $5\frac{1}{2}$ grams. As a rule, they measure about 30 mm. in height; 7 or 8 mm. in thickness; and have a breadth at the base of about 45 mm. They augment in volume during digestion and also increase in size during the acute infectious diseases and in intoxications such as uremia.

Colour and consistency.—The suprarenal glands as seen from the surface have a yellowish or brownish-yellow colour. Upon section the colour of the surface layer appears a little darker while the central part of the gland appears greyish or, if it contains much blood, of a reddish colour. If some little time has elapsed since death, the central part of the suprarenal may be almost black in colour.

The glands are very fragile and softer in consistency than the thyroid or thymus. As a rule, they are harder and more resistant than the fat of the adipose capsule and may be thus readily detected in it.

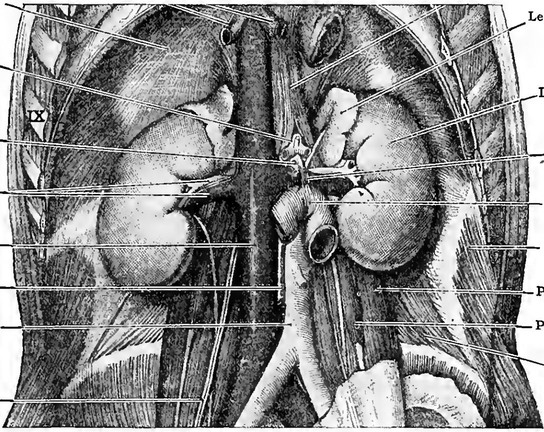
Form.—The suprarenal glands are markedly flattened dorso-ventrally. Their surfaces are roughened by irregular tubercles and furrows. They vary considerably in shape (figs. 1077, 1078). The *right* gland is usually somewhat triangular in outline while the *left* is, as a rule, semilunar. Each gland has an anterior and a posterior surface, a base and an apex, a medial and a superior margin.

The **anterior surface** [facies anterior] may be either convex or concave, and look ventro-laterally. It is marked by a distinct transverse, oblique, or nearly vertical fissure, the **hilus suprarenalis.** At this point a small artery enters and the principal suprarenal vein takes exit from the gland. These surfaces are in relation with different organs on the right and left sides.

The anterior surface of the *right* gland is in the greatest part of its extent in contact with the posterior surface of the liver, upon which it produces the suprarenal impression. The medial edge of this surface is overlapped, cephalically by the inferior vena cava and caudally by the duodenum. The gland is situated between the two layers of the coronary ligament, in most cases, in direct contact with the liver to which it is bound by loose connective tissue; but, at times, the peritoneum which covers the ventral surface of the kidney extends for a greater or less distance between the suprarenal and the liver.

The anterior surface of the *left* gland, in some cases, may be in contact in its cephalic part with the left lobe of the liver and also, at times, with the spleen. The middle and major part lies against the fundus and cardiac end of the stomach, while caudally the suprarenal is often

Fig. 1080.—Ventral View of the Suprarenal Glands, in Situ. × $\frac{1}{3}$. (From Toldt's Atlas.)



crossed by the tail of the pancreas and the splenic artery and vein. The whole or a large part of the anterior surface of the left suprarenal is covered by the parietal peritoneum of the omental bursa.

The **posterior surface** [facies posterior] of both the suprarenals is distinctly smaller than the anterior surface. It is flat or convex and looks dorso-medially.

It is in relation with the lumbar part of the diaphragm, to which it is bound by connective tissue, but from which it is separated by an extension of the renal adipose capsule.

The **base** [basis gl. suprarenalis] is a narrow elongated surface distinctly hollowed out, which lies in contact with the superior extremity of the kidney or its medial margin, cephalic to the hilus.

This surface looks dorsally, laterally, and somewhat caudally with the result that it extends farther on the anterior surface than on the posterior surface of the kidney.

The **medial border** [margo medialis] is sharp, thin, and irregularly convex. It extends more or less vertically to meet the superior border.

On the *right* it lies dorsal to the inferior vena cava cephalically and to the duodenum caudally and is close to, if not in contact with, the sympathetic cœliac ganglion. On the *left* the medial border lies dorsal to the stomach and caudally may be crossed by the pancreas and splenic vessels. It is in close proximity to the aorta and the cœliac sympathetic ganglion.

The **superior border** [margo superior] is sharp and thin and differs somewhat on the two sides.

On the *right* it is irregular, straight or convex, and extends, dorsal to the liver, obliquely cephalo-medially to meet the medial border in a more or less acute point, **apex suprarenalis,** which is directed cephalically and somewhat medially. On the *left* the superior border is irregularly convex in shape and nearly horizontal in direction. It passes gradually over into the medial border without the intervention of any distinct apex. It is dorsal to the stomach and in some cases comes into contact with the spleen.

Accessory suprarenal glands [gl. suprarenales accessoriæ] are often found in the connective tissue in the neighbourhood of the principal organs. They are also sometimes found in the kidney near the internal spermatic veins and in the region of the sexual glands. The structures recorded as accessory suprarenal glands may be complete suprarenal glands composed of the cortex and medulla or they may be composed of the cortex only. Masses of chromaffin tissue representing the medulla are sometimes spoken of as accessory suprarenals but these more properly belong with the chromaffin system.

Complete *absence* of the suprarenal glands has been recorded only in monsters with grave cranial and cephalic defects. Absence of one gland has been found and the fusion of the two has also been noted.

Structure.—The suprarenal glands are surrounded by a thin and tough fibrous *capsule* composed mainly of white fibrous connective tissue. From the capsule numerous trabeculæ are given off which pervade the gland and form septa between the groups and rows of cells. Within the capsule the suprarenal is composed of an external firmer yellowish layer, the *cortex* [substantia corticalis], and an internal softer whitish layer, the *medulla* [substantia medullaris] (fig. 1079).

On section the cortex is seen to form by far the greater part of the gland and it is marked radially from the centre toward the surface by darker and lighter streaks. In its deepest part it is brownish yellow or red and is usually slightly torn where it joins the medulla. As frequently found at autopsy the cortex is separated from the medulla by a slit filled with a soft dark brown or blackish mass caused by the breaking down of the deeper layer of the cortex. The medulla is a greyish, spongy, vascular mass which often because of its blood content appears of a reddish or reddish-brown colour.

The cortical portion of the gland is subdivided into a superficial, glomerular portion, **zona glomerulosa**; an intermediate, fascicular portion, **zona fasciculata**; and an internal reticular portion, **zona reticulata,** according to the peculiar grouping of the gland cells in these respective areas.

In the glomerular zone the cells are of irregular columnar shape, and grouped in coiled columns. In the fascicular zone the cells, which are of polyhedral shape, are arranged in more or less regular parallel columns, while in the reticular zone the cells form trabeculæ or groups. The reticular connective-tissue framework, continuous with the capsule, surrounds the cell masses and cell columns of the several zones. The cells of the medulla show an affinity for chromic acid—chromaffin cells—and are grouped in irregular masses separated by septa of the reticulum and venous spaces. The arteries form a close-meshed plexus in the capsule from which branches run more or less parallel toward the medulla forming a network around the cell columns of the glomerular and fascicular zones. This opens into a venous plexus of wide calibre in the reticular zone, which is connected with the vessels of the medulla. Small medullary arteries pass through the cortex without branching to end in a venous plexus in the medulla. The abundant wide-meshed venous sinuses in the medulla (sinusoids) join to form small central veins which converge toward the centre of the medulla to form the large central vein.

Vessels and nerves.—The suprarenal glands are richly supplied with vessels. The arteries are three—superior, middle and inferior.

From the inferior phrenic artery, the **superior suprarenal artery** arises and passes toward the superior border of the gland. From the aorta the **middle suprarenal artery** takes origin between the cœliac and superior mesenteric arteries and passes toward the medial border of the suprarenal. It is a branch of this artery which is usually found at the hilus along with the central vein. From the renal artery the **inferior suprarenal artery** arises and reaches the suprarenal near its base. These three arteries anastomose with one another and form a plexus in the capsule of the suprarenal from which the arteries for the interior of the gland are derived.

The large central vein from the medulla passes through the cortex to emerge at the hilus as the suprarenal vein, **vena suprarenalis.** The right vein opens usually into the inferior vena cava, where there is a valve, the left into the left renal vein. There may also be small branches connecting with the phrenic or the right renal vein.

The **lymphatics** of the suprarenals are very numerous and are represented by a superficial plexus in the capsule and a deep plexus in the medulla. These are connected by numerous anastomoses. They pass medially and converge into a number of trunks on each side which empty into lymph-glands situated along the aorta near the origin of the renal arteries. On the left side there is also the communication through the diaphragm with a posterior mediastinal gland.

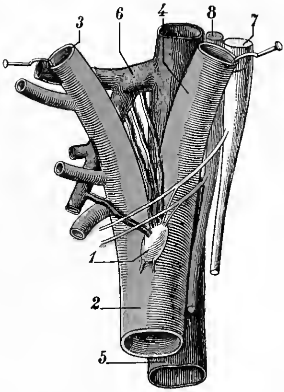
The **nerves** are derived chiefly from the cœliac and renal plexuses but include filaments from the splanchnics, and according to some authors from the phrenic and vagus nerves also. These numerous fine twigs connect with the gland in many different places and form a rich plexus. Branches are distributed to the capsule, to the cortical substance, and to the medullary substance. Groups of sympathetic ganglion cells are found in the medullary part of the gland.

Development.—The suprarenal glands of mammals have their origin from two sources. The cortical mesodermic portion of the glands arises in early embryos as buds extending from tbe mesothelium on both sides of the root of the mesentery into the mesoderm ventral to the aorta. A little later these become definite organs completely separated from the cœlomic epithelium and are soon vascularised, but the central vein does not become visible until considerably later. The suprarenal glands after their separation from the peritoneum form a ridge on either side of the posterior wall of the cœlom medial to the mesonephros. Some little time after the origin of the cortical portion of the gland has undergone cellular differentiation and has become surrounded by a delicate capsule, the medullary portion is formed by the migration of masses of sympatho-chromaffin cells from the medial side toward the centre of the organ so that they surround the central vein as the anlage of the medullary nucleus. They penetrate the cortical portion of the gland as development proceeds and become completely surrounded by it. These migrating masses are entirely or for the most part of chromaffin formative cells derived from the ectoderm. They are clearly differentiated from the cortical cells by their small size and darker colour, in stained sections. Migration of these cell masses into the gland seems to be continued even after birth. The differentiation of the cortex into three layers occurs late in development. The suprarenal glands are relatively large in fœtal life; and their relation to the kidneys is secondarily acquired.

THE GLOMUS CAROTICUM

The **carotid bodies** [glomera carotica] are small ovoid or spherical bodies found at or near the point where the common carotid arteries divide into the internal and external carotids (fig. 1081). They are usually on the dorsal and medial side of the angle of bifurcation of the arteries. There is ordinarily one body on

Fig. 1081.—The Glomus Caroticum (Carotid Body). (From Testut, after Princeteau.) 1, Carotid body; 2, 3, 4, common, external and internal carotids; 5, int. jugular; 7, inf. cervical sympathetic ganglion; 8, vagus.

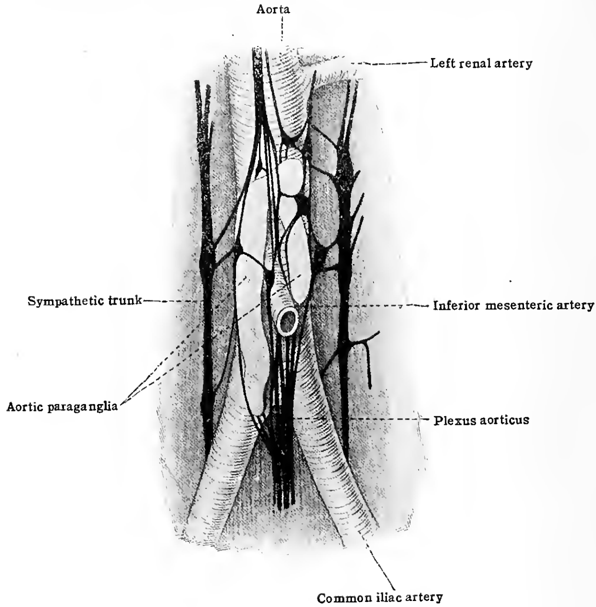


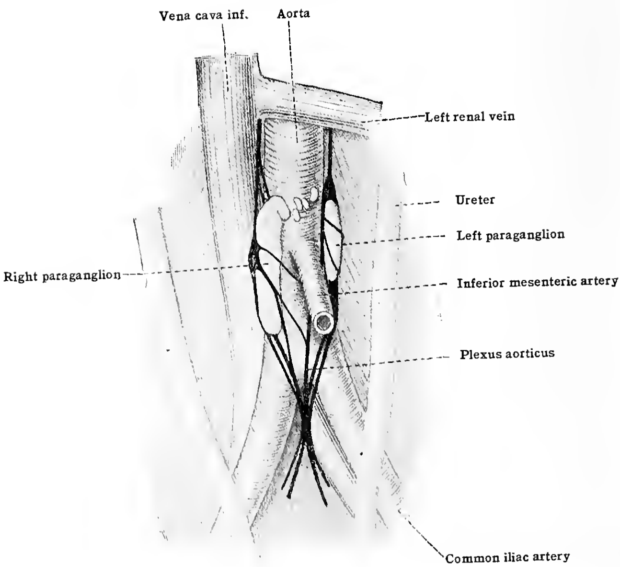
each side, 5 or 6 mm. in length and 2 or 3 mm. in thickness. It is reddish-yellow in colour and is attached to the carotid by fibrous tissue and by the vessels and nerves which enter it. A small special fibrous band may sometimes be recognised binding it to the common, external or internal carotid artery.

The carotid body or gland is composed of two essential parts: (1) round, oval, or polyhedral epithelial cells which contain chromaffin granules, and are bound together by a mass of fibrous connective tissue; and (2) a rich plexus of capillaries and sinusoids forming a mesh. Large lymph-vessels surround the outside of the gland. The carotid gland has a very abundant nerve supply, mostly from the sympathetic system, and ganglion cells are found in it. It may receive twigs from the superior laryngeal, hypoglossal, or glossopharyngeal nerves, as recorded by some observers.

The *size* of the carotid body varies considerably. At times tbe carotid bodies are absent; in other cases they are so small that they can be detected only in microscopic sections; occasionally they are 8 mm. in length by 4 or 5 mm. in thickness. Rarely the carotid bodies may be broken up into two or more smaller masses bound together by connective tissue. The carotid body may be larger in old individuals due to an increase in the connective tissue or vascular elements with a corresponding decrease in the epithelial cells. The origin is probably from sympatho-chromaffin cells but some investigators believe that they are derived from the endothelium of the blood-vessels and others that they arise from the endoderm of a branchial pouch.

Figs. 1082 and 1083.—Aortic Paraganglia. (Zuckerkandl.)





THE AORTIC PARAGANGLIA

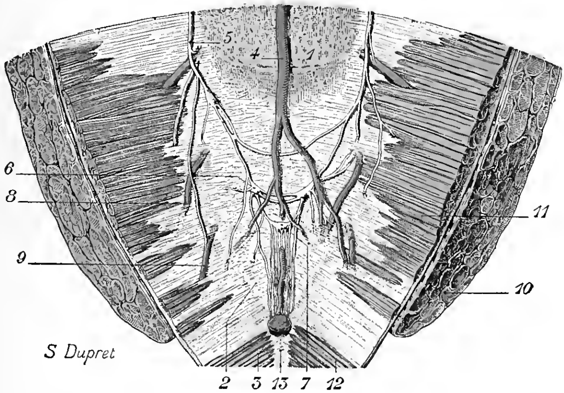
The **abdominal chromaffin bodies,** the **paraganglia aortica,** or **paraganglia lumbalia,** are situated on each side of the abdominal aorta near the point of origin of the inferior mesenteric artery (figs. 1082, 1083). They are elongated, flattened, ovoid bodies, softer and greyer than the lymphatic glands and extremely variable in size.

They measure, as a rule, between 6 and 12 mm. in length, although occasionally as long as 30 mm. or as short as 1 mm. They may be connected by transverse bands in front of the aorta or occur as scattered nodules in this situation. They are intimately related to the aortic sympathetic plexus and at least one of them is uniformly found. They consist of a mass of chromaffin cells surrounded by a rich capillary plexus and contain many nerve fibres and nerve cells.

THE GLOMUS COCCYGEUM

The **coccygeal body** [glomus coccygeum] is a small, spherical greyish-red body consisting of a median unpaired mass 2 to 3 mm. in diameter, single or divided into three to six connected nodules. It is placed immediately ventral to the tip

Fig. 1084.—Coccygeal Gland, in Situ. 1, Sacrum; 2, coccyx; 3, coccygeal gland; 4, middle sacral artery; 5, 6, sacral sympathetic; 7, ganglion impar.; 8, last sacral; 9, coccygeal nerve; 10, gluteus maximus; 11, ischio-coccygeus; 12, levator ani; 13, ano-coccygeal raphe. (Testut.)



of the coccyx, imbedded in fat and in relation with the terminal branch or branches of the medial sacral artery, with the ischio-coccygeal muscles, and fibres of the sympathetic nervous system (fig. 1084).

It is composed of groups of epithelial cells bound together by a mass of fibrous tissue and containing a plexus of sinusoidal capillary vessels in intimate relation with the cells. Numerous nerve fibres also enter the gland. It is not certain that the cells are chromaffin in character or that the coccygeal body has an internal secretion.

SECTION XIII

CLINICAL AND TOPOGRAPHICAL ANATOMY

REVISED FOR THE FIFTH EDITION

By JOHN MORLEY, Ch.M., F.R.C.S.

HONORARY SURGEON, ANCOAT'S HOSPITAL, MANCHESTER; LECTURER IN CLINICAL ANATOMY, MANCHESTER UNIVERSITY

THE HEAD

IN describing the clinical and topographical relations, the divisions of the body will be successively considered in the following order: head, neck, thorax, abdomen, pelvis, back, upper and lower extremities.

The bony landmarks of the head will first be considered, followed by a separate description of the cranium and the face.

Bony landmarks.—These should be studied with the aid of a skull, as well as on the living subject. Beginning in front is the **nasion,** a depression at the root of the nose, and immediately above it, the **glabella,** a slight prominence joining the two supraciliary arches. These points mark the remains of the frontal suture, and the junction of the frontal, nasal, and superior maxillary bones and one of the sites of a meningocele. In the middle line, behind, is the external occipital protuberance, or **inion,** the thickest part of the vault, and corresponding internally with the meeting-point of six sinuses. A line joining the inion and glabella corresponds to the sagittal, and occasionally the frontal, suture, the falx cerebri, the superior sagittal sinus, widening as it runs backward, and the longitudinal fissure of the brain. From the inion the superior nuchal lines pass laterally toward the upper and back part of the base of the mastoid processes, and indicate the first or so-called horizontal part of the transverse (lateral) sinus.

This vessel usually presents a varying curve upward and runs in the tentorium. The second or sigmoid portion turns downward on the inner surface of the mastoid, then forward, and lastly downward again to the jugular foramen, thus describing the double curve from which this part takes its name. In the jugular foramen the vessel occupies the posterior compartment; its junction with the internal jugular is dilated and forms the bulb. A line curved downward and forward from the upper and back part of the base of the mastoid, reaching two-thirds of the way down toward the apex, will indicate the second part of the sinus. The spot where it finally curves inward to the bulb would be about 1.8 cm. ($\frac{3}{4}$ in.) below and behind the meatus. The two portions of the transverse sinus meet at the asterion laterally; at the entry of the superior petrosal sinus medially. The right transverse sinus, the larger, is usually a continuation of the superior sagittal sinus, and, therefore, receives blood chiefly from the cortex of the brain; the left, arising in the straight sinus, drains the interior of the brain and the basal ganglia. Each transverse sinus receives blood from the temporal lobe, the cerebellum, diploë, tympanic antrum, internal ear, and two emissary veins, the mastoid and posterior condylar.

About 6.2 cm. ($2\frac{1}{2}$ in.) above the external occipital protuberance is the **lambda,** or meeting of the sagittal and lambdoidal sutures (posterior fontanelle, small and triradiate in shape). It is useful to remember, as guides on the scalp to the above two important points, that the lambda is on a level with the supraciliary ridges, and the external occipital protuberance on one with the zygomatic arches.

Below the external occipital protuberance, between it and the foramen magnum, an **occipital,** the commonest form of cranial **meningoceles,** makes its appearance. It comes through the median fissure in the cartilaginous part of the squamous portion of the bone.

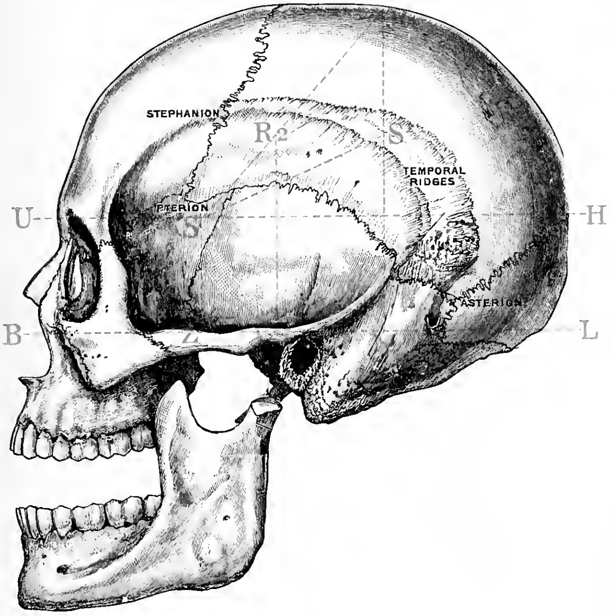
The point of junction of the occipital, parietal, and mastoid bones, the **asterion,** is placed about 3.7 cm. (1½ in.) behind and 1.2 cm. (½ in.) above the centre of the auditory meatus (fig. 1085). It indicates the site of the posterior lateral fontanelle and just below it the superior nuchal line terminates. The **bregma,** or junction of the coronal, sagittal, and, in early life, the frontal suture (anterior fontanelle, large and lozenge-shaped), lies just in front of the centre of a line drawn transversely over the cranial vault from one pre-auricular point to the other (fig. 1090). The bregmatic fontanelle normally closes before the end of the second year. The lambdoid fontanelle is closed at birth. The **pterion,** or junction of the frontal and sphenoid in front, parietal and squamous bones behind, lies in the temporal fossa, 3.7 to 5 cm. (1½ to 2 in.) behind the zygomatic process of the frontal, and about the same distance above the zygoma (fig. 1085). This spot also gives the position of the trunk and the anterior and larger division of the middle meningeal artery (fig. 1090), the Sylvian point and divergence of the limbs of the lateral (Sylvian) fissure, the insula (island of Reil), and middle cerebral artery. It, further, corresponds to the anterior lateral fontanelle. On the side of the skull the **zygomatic arch,** the **temporal ridge,** and **external auditory meatus** need attention. That important landmark, the **zygomatic arch,** wide in front where it is formed by the zygomatic (malar), narrowing behind where it joins the temporal, gives off here three roots, the most anterior marked by the eminentia articularis, in front of the mandibular (glenoid) fossa, the middle behind this joint, while the posterior curves upward and backward to be continuous with the temporal ridge. Within the zygomatic arch lie **two fossæ** separated by the infra-temporal (pterygoid) ridge: above is the **temporal,** with the muscle and deep temporal vessels and nerves; below is the **infra-temporal** or **zygomatic** fossa, with the lower part of the temporal muscle, the two pterygoids, the internal maxillary vessels, and the mandibular division of the fifth. To the upper border of the zygomatic arch is attached the temporal fascia, to its lower, the masseter. Its upper border marks the level of the lower lateral margin of the cerebral hemisphere. A point corresponding to the middle root of the zygoma, immediately in front of the tragus, and on a level with the upper border of the bony meatus, is called the **pre-auricular point.** Here the superficial temporal vessels and the auriculo-temporal nerve cross the zygoma, and a patient's pulse may be taken by the anæsthetist. The lower end of the central (Rolandic) fissure lies 5 cm. (2 in.) vertically above this point. The **temporal ridge,** giving origin to the temporal fascia, starts from the zygomatic process of the frontal, and becoming less distinct, curves upward and backward over the lower part of that bone, crosses the coronal suture, traverses the parietal bone, curving downward and backward to its posterior inferior angle. Here it passes on to the temporal, and passing forward over the external auditory meatus, is continuous with the posterior root of the zygoma. Below the root of the zygoma will be felt the temporo-mandibular joint, and when the mouth is opened, the condyle will be felt to glide forward on the eminentia articularis, leaving a well-marked depression behind.

The **external auditory meatus,** measured from its opening on the concha to the membrane, is about 2.5 cm. (1 in.) in length; if from the tragus, 3.7 cm. (1½ in.). Its long axis is directed medially and a little forward with a slight convex curve upward, most marked in its centre. Between the summit of this curve and the membrane is a slight recess in which foreign bodies may lodge. The lumen is widest at its commencement, narrowest internally. To bring the cartilaginous portion in line with the bony, the pinna should be drawn well upward and backward. In the bony portion the skin and periosteum are intimately blended, thus accounting for the readiness with which necrosis occurs. The sensibility of the meatus is explained by the two branches sent by the auriculo-temporal nerve. The fact that the deeper part is supplied by the auricular branch of the vagus explains the vomiting and cough occasionally met with in affections of the meatus.

The **anterior inferior angle of the parietal bone,** and its great importance as a landmark, have already been noted. The **posterior inferior angle** of this bone (grooved by the transverse (lateral) sinus) lies a little above and behind the base of the mastoid, on a level with the roots of the zygoma (fig. 1085). Just below and in front of the tip of the mastoid the **transverse process of the atlas** can be made out in a spare subject.

In front, the circumference of the **bony orbit** can be traced in its whole extent. The *supraorbital notch* lies at the junction of the medial and intermediate thirds of the supraorbital arch. When this notch is a complete foramen, its detection is much less easy. To its medial side the *supratrochlear nerve* and *frontal arterd* cross the supraorbital margin; like the supraorbital, this nerve and vessel lie, at first, in close relation with the periosteum. The frontal artery is one of the chief blood-supplies to flaps taken from the forehead. Owing to the paper-like thinness of the bones on the medial wall of the orbit, e. g., lacrimal, ethmoid, and body of sphenoid, and the mobility of the skin, injuries which are possibly penetrating ones, as from a slate-pencil, ferrule, etc., are always to be looked upon with suspicion. After a period of latency of symptoms, infection of the membranes and frontal abscess have often followed. Above the supraorbital margin is the supraciliary arch, and higher still the frontal eminence [tuber frontale].

FIG. 1085.—THE SKULL, SHOWING KRÖNLEIN'S METHOD OF CRANIOCEREBRAL TOPOGRAPHY.



THE CRANIUM

Under this heading will be considered the scalp, the bony sinuses, craniocerebral topography and the hypophysis.

The scalp.—The importance of the **scalp** is best seen from an examination of its **layers** (fig. 1086). These are—(1) **skin**; (2) **subcutaneous fat** and **fibrous tissue**; (3) the **epicranius** (occipito-frontalis) and **aponeurosis**; (4) the **subaponeurotic layer** of connective tissue; (5) the **pericranium.**

The first three layers are connected and move together. The thick skin supported by the dense fibrous subcutaneous layer and epicranial aponeurosis, is well adapted to protect the underlying skull from the effects of trauma, and in this connection the mobility of the first three layers on the subaponeurotic areolar tissue is important. A scalp wound does not gape widely unless it involves the epicranial aponeurosis, in which case it involves the subjacent **"dangerous area"** of the scalp, so-called because pus in this layer may spread widely underneath the scalp and even give meningeal infection by spreading through the diploic or emissary veins. In the process of scalping (whether performed by the knife or by the hair being caught in machinery), separation takes place at this subaponeurotic layer which is loose, delicate and devoid of fat.

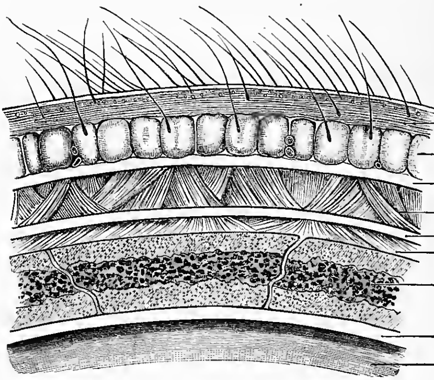
The numerous **sebaceous glands** frequently give rise to cysts in the scalp.

The **epicranius and aponeurosis** have been described elsewhere (p. 336).

The **pericranium** differs from periosteum elsewhere in that it gives little nourishment to the bone beneath, which derives most of its blood-supply from the meningeal vessels. After necrosis of the skull there is no tendency to the formation of an involucrum of new subperiosteal bone as in the long bones. The pericranium is firmly adherent to the sutures of the skull bones, so that any subpericranial effusion of blood or pus is limited by the sutures.

Of the **vessels of the scalp,** the *arteries*, arising in the anterior region from the internal, in the posterior from the external, carotid, are peculiar in their position. Thus they lie superficial to the deep fascia, which is here represented by the aponeurosis (fig. 1086). From this position arises the fact that a large flap of scalp may be separated without perishing, as it carries its own blood-vessels. From the density of the layer in which the vessels run they cannot retract and are difficult to seize, hæmorrhage thus being free. Finally, from their position over closely adjacent bone, ill-applied pressure may easily lead to sloughing. A practical point with regard to the veins is given below. The *lymphatics* from the front of the scalp drain into the anterior auricular and parotid, those behind into the posterior auricular, occipital and deep cervical nodes. The *nerves* are derived from all three divisions of the trigeminus, from the

Fig. 1086.—Section through the Scalp, Skull, and Dura Mater. (Tillaux.)



facial (motor) and also from three branches of the second and third cervical. The supply from the fifth explains the neuralgia in acute iritis, glaucoma, and herpes frontalis, and also the pains shooting up from the front of the ear in late cancer of the tongue.

The emissary veins.—These are communications between the sinuses within, and the veins outside, the cranium. Most of them are temporary, corresponding to the chief period of growth of the brain. Thus in early life, when the development of the brain has to be very rapid, owing to the approaching closure of its case, a free escape of blood is most essential, especially in children, with their sudden explosions of laughter and passionate crying.

The gravity of these emissary veins and their free communications with others are shown by the readiness with which they become the seat of thrombosis, and thus of blood-poisoning, in cranial injuries, erysipelas, infected wounds of the scalp, and necrosis of the skull. They include the following:

1. Vein through the foramen cæcum, between the anterior extremity of the superior sagittal sinus and the nasal mucous membrane. The value of this temporary outlet is well seen in the timely profuse epistaxis of children. Other more permanent communications between the skull cavity and nasal mucous membrane pass through the ethmoid foramina. The fact that the nasal mucous membrane is loose and ill-supported on the nasal conchæ (turbinate bones) allows its vessels to give way readily, and thus forms a salutary safeguard to the brain, warding off many an attack of apoplexy. 2. Vein through the mastoid foramen, between the transverse

(lateral) sinus and the posterior auricular and occipital veins. This is the largest, the most constant, and the most superficial of the emissary veins. Hence the old rule of applying blisters or leeches over it in cerebral congestion. 3. Vein through the posterior superior angle of the parietal between the superior sagittal sinus and the veins of the scalp. 4. Vein through the condyloid foramen between the transverse (lateral) sinus and the deep veins of the neck. 5. Vein through the hypoglossal canal between the occipital sinus and the deep veins of the neck. 6. Ophthalmic veins communicating with the cavernous sinus and the angular vein. These veins may be the source of fatal blood-poisoning, by conveying out of reach septic material, in acute periostitis of the orbit, or in osteitis, of dental origin, of the jaws. 7. Minute veins through the foramen ovale between the cavernous sinus and the pharyngeal and pterygoid veins. 8. Communications between the frontal diploic and supraorbital veins, between the anterior temporal diploic and deep temporal veins, and between the posterior temporal and occipital diploic veins and the transverse sinus. In addition to the veins specially mentioned, the scalp and sinuses communicate by numerous diploic veins, by those in the inter-sutural membrane, and through sutures before their obliteration, as already explained.

Structure of cranium.— **Two layers** and intervening **cancellous tissue.** Each layer has special properties. The **outer** gives thickness, smoothness, and uniformity, and, above all, elasticity. The **inner** is whiter, thinner, less regular— e. g. the depressions for vessels, Pacchionian bodies, dura mater, and brain. The **diploë,** formed by absorption after the skull has attained a certain thickness, reduces the weight of the skull without proportionately reducing its strength, and provides a material which will prevent the transmission of vibrations.

A blow on the head may fracture the internal layer only, the external one and diploë escaping. This is difficult to diagnose, and thus it is impossible to judge of the severity of a fracture from the state of the external layer. This may be whole, or merely cracked, while the internal shows many fragments, which may set up meningitis or other mischief. It is usual to find more extensive splintering of the inner than of the outer layer (table).

The average **thickness** of the adult skull-cap is about 5 mm. ($\frac{1}{5}$ in.). (Holden.) The thickest part is at the external occipital protuberance, where the bone is often 1.8 cm. ($\frac{3}{4}$ in.) in thickness. The thinnest part of the skull vault is over the temporal part of the squamous. The extreme fragility of the skull here is partly compensated for the by thickness of the soft parts; these two facts are always to be remembered in the diagnosis of a fracture of the skull here, after a slight injury. Other weak spots are the medial wall of the orbit, the cerebellar fossæ, and that part of the middle fossa corresponding to the glenoid cavity.

Anatomical conditions tending to minimise the effects of violence inflicted upon the skull.— (1) The **density** and **mobility of the scalp.** (2) The **dome-like shape of the skull.** This is calculated to bear relatively hard blows and also to allow them to glide off. (3) The **number of bones** tends to break up the force of a blow. (4) The **sutures** interrupt the transmission of violence. (5) The **inter-sutural membrane** (remains of fœtal periosteum) acts, in early life, as a linear buffer. (6) The **elasticity of the outer layer** (table). (7) The **overlapping of some bones,** e. g. the parietal by the squamous; and the alternate bevelling of adjacent bones, e. g. at the coronal suture. (8) The **presence of ribs,** or **groins,** e. g. (*a*) from the crista galli to the internal occipital protuberance; (*b*) from the root of the nose to the zygoma; (*c*) the temporal ridge from orbit to mastoid; (*d*) from mastoid to mastoid; (*e*) from external occipital protuberance to the foramen magnum. (9) **Buttresses,** e. g. zygomatic processes and the greater wing of the sphenoid. (10) The **mobility** of the head upon the spine.

THE BONY SINUSES

Frontal.—When well developed, the frontal sinuses may reach 5 cm. (2 in.) upward and 3.7 cm. ($1\frac{1}{2}$ in.) laterally, occupying the greater part of the vertical portion of the frontal bone. When very small, they scarcely extend above the nasal process. In any case, they are rarely symmetrical. The average dimensions of an adult frontal sinus are 3.7 cm. ($1\frac{1}{4}$ in.) in height, 2.5 cm. (1 in.) in breadth, and 1.8 cm. ($\frac{3}{4}$ in.) in depth. (Logan Turner.) The sinuses are separated by a septum. The posterior wall is very thin. Each sinus narrows downward into the infundibulum. This is 'deeply placed, at the back of the cavity, behind the frontal (nasal) process of the maxilla and near the medial wall of the orbit. Its termination in the middle meatus is about on a level with the palpebral fissure.' (Thane and Godlee.) Its direction is backward.

The communication of these sinuses with the nose accounts for the frontal headache, the persistence of polypi and ozæna, and the fact that a patient with a compound fracture opening up the sinuses can blow out a flame held close by.

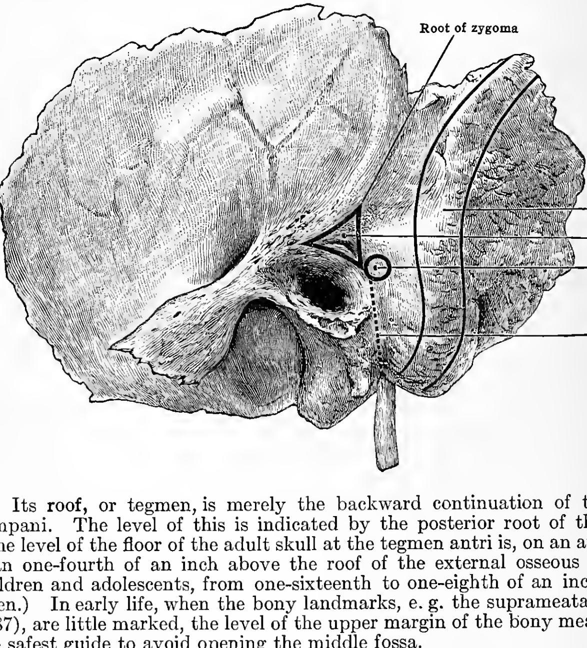
To open the frontal sinus, while the incision which leaves the least scar is one along the shaved eyebrow, superficial laterally so to avoid the supraorbital nerve and vessels, running a little downward at the medial end, it is always to be remembered that, where the sinuses are little developed, this or a median incision may open the cranial cavity. To avoid this complication the sinus should always be opened at a spot vertically above the medial angle.

The development of these by the twentieth or twenty-fifth year may render a fracture here much less grave in the adult than would otherwise be the case, the inner layer (table), if now separated from the outer, protecting the brain. Mr. Hilton showed that the absence of any external prominence here does not necessarily imply the absence of a sinus, as this may be formed by retrocession of the internal layer. In old people these sinuses may enlarge by the inner layer following the shrinking brain. Again, prominence of the supraciliary and frontal eminences does not necessarily point to the existence of a sinus at all, being due merely to a heaping up of bone.

The **mastoid** cells are arranged in two groups, of the utmost importance in that frequent and fatal disease, inflammation of the middle ear:—(A) The **upper,** or **'antrum,'** present both in early and late life, horizontal in direction, closely adjacent to and communicating with the tympanum. (B) The **lower,** or **vertical.** This group is not developed in early life.

A. **Tympanic antrum** (fig. 1088).—This is a small chamber lying behind the tympanum, into the upper and back part of which (epitympanic recess) it opens. Its size varies, especially with age. Almost as large at birth, it reaches its maximum (that of a pea) about the third or fourth year. After this its size usually diminishes somewhat, owing to the development of the encroaching bone around

Fig. 1087.—Temporal Bone, showing Suprameatal Triangle. (Barr.)
The lower part of the transverse sinus is here placed too far back to be relied upon with constant accuracy.

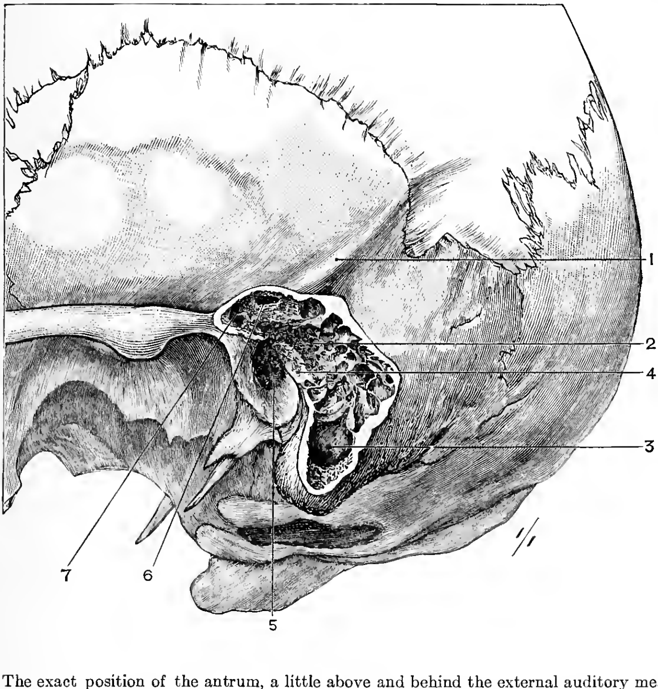


it. Its **roof,** or tegmen, is merely the backward continuation of the tegmen tympani. The level of this is indicated by the posterior root of the zygoma. 'The level of the floor of the adult skull at the tegmen antri is, on an average, less than one-fourth of an inch above the roof of the external osseous meatus; in children and adolescents, from one-sixteenth to one-eighth of an inch.' (Macewen.) In early life, when the bony landmarks, e. g. the suprameatal crest (fig. 1087), are little marked, the level of the upper margin of the bony meatus will be the safest guide to avoid opening the middle fossa.

The **lateral wall** of the antrum is formed by a plate descending from the squamous bone. This is very thin in early life, but as it develops by deposit under the periosteum, the depth of the antrum from the surface increases. Macewen gives the average of the depth as varying from one-eighth to three-fourths of an inch. The thinness of the outer wall in early life is of practical importance. It allows of suppuration making its way externally—subperiosteal mastoid abscess. This will be facilitated by any delay in the closure of the petro- and masto-squamosal sutures, by which this thin plate blends with the rest of the temporal bone. Further, by the path of veins running through these sutures or their remnants, infection may reach such sinuses as the inferior petrosal. The sutures normally close in the second year after birth. Through the **floor,** the antrum communicates with the lower or vertical cells of the mastoid. This floor is on a lower level than the opening into the tympanum, and thus drainage of an infected antrum is difficult, fluid finding its way more readily into the lower cells. **Behind** the mastoid antrum and cells is the bend of the sigmoid part of the transverse (lateral) sinus, with its short descending portion (fig. 1087). The average distance of the sinus from the superior meatal triangle is 1 cm. ($\frac{2}{5}$ in.). It may be further back; on the other hand, it may come within 2 mm. ($\frac{1}{12}$ in.) from the meatus, and even overlap the outer wall of the antrum.

Fig. 1088.—The Mastoid Antrum and Cells. (Jacobson and Steward.)

1. Posterior root of zygoma forming the supramastoid or suprameatal crest and upper part of Macewen's triangle. 2. Antrum, and in front of it, the epitympanic recess. 3. Vertical cells of the mastoid. 4. Ridge on the inner wall of the tympanum, caused by the facial canal. 5. Fenestræ on inner wall of tympanum, indicated in shadow. 6. A deficiency present in the tegmen tympani, enlarged with a small osteotrite to emphasise the thinness of the roof of the antrum and tympanum. 7. Cells extending, in this case, even into the root of the zygoma.



The exact position of the antrum, a little above and behind the external auditory meatus is represented by Macewen's 'suprameatal triangle.' This is a triangle bounded by the posterior root of the zygoma above, the upper and posterior segment of the bony external meatus below, and an imaginary line joining the above boundaries (fig. 1087). "Roughly speaking, if the orifice of the external osseous meatus be bisected horizontally, the upper half would be on the level of the mastoid antrum. If this segment be again bisected vertically, its posterior half would again correspond to the junction of the antrum and middle ear, and immediately behind this lies the suprameatal fossa.' (Macewen.) When opening the antrum through this triangle, the operator should work forward and medially, so as to avoid the transverse sinus (fig. 1087); while, to avoid the facial nerve (fig. 1087), he should hug the root of the zygoma and the upper part of the bony meatus as closely as possible. The level of the base of the brain will be a few lines above the posterior root of the zygoma (fig. 1089) and about 6 mm. ($\frac{1}{4}$ in.) above the roof of the bony meatus. (Macewen.)

B. **The lower or vertical cells of the mastoid** are developed later than is the antrum, and vary much in their contents. The condition of the mastoid cells varies very widely. They may be numerous (fig. 1088) or few. In the latter case they are replaced by diploë, or by bone which is unusually dense, without necessarily any pathological change. Hence mastoids have been classified as pneumatic, diploëtic, or sclerosed.

As part of the surgical anatomy of this most important region, the different paths by which infection of the tympanum and antrum may travel should be glanced at. The most important are:—(1) **Upward**: either by advancing caries or by infection of veins going to the superior petrosal sinus, or through the tegmina to the membranes; an abscess in the overlying temporal lobe, usually the middle and back part. (2) **Backward**: the transverse (lateral) sinus and cerebellum (abscess of the front and outer part of the lateral lobe) are reached in the same ways as those given above, the mastoid vein being the one chiefly affected here. Macewen has shown that the bony wall of the sinus, like those of the tegmina and the aqueduct of Fallopius, may be naturally imperfect. (3) **Downward**: where the vertical cells are well developed (fig. 929) mischief may reach the mastoid notch and cause deep-seated inflammation beneath the sterno-mastoid. (v. Bezold's abscess.) (4) **Lateralward**: the explanation of this, in early life, has been given above. (5) **Medialward**: the facial nerve, or by the fenestra ovalis; the labyrinth is now in danger. When the internal ear and auditory nerve are affected, infection finds another path to the cerebellar fossa.

The **sphenoidal** sinuses are less important surgically, but these points should be remembered:—(1) Fracture through them may lead to bleeding from the nose, which is thus brought into communication with the middle fossa; (2) the communication of their mucous membrane with that of the nose may explain the inveteracy of certain cases of polypi and ozæna; (3) here and in the frontal sinuses very dense exostoses are sometimes formed. Before any operative attack on these sinuses is undertaken, their most important relations should be remembered. Thus **above** are the olfactory and optic nerves, the pituitary body, and front of the pons. **Externally** lie the cavernous sinus and superior orbital (sphenoidal) fissure. **Below** is the roof of the nose.

The **ethmoidal** and **maxillary sinuses** are considered later in connection with the Nose. See also the sections on Osteology and Respiratory System.

CRANIO-CEREBRAL TOPOGRAPHY

To make as clear as possible the points of practical importance which have, of late years, been put on a definite basis, and which the surgeon may have to recall and act upon at very short notice, cranio-cerebral topography will be spoken of under the following headings: A. **Relation of the brain as a whole to the skull.** B. **Relation of the chief sulci and gyri to the skull.** C. **Localisation of the chief sulci and gyri.** Before alluding to the above, it is necessary to say distinctly that the following surface-markings and points of guidance are only approximately reliable, for the following reasons: (1) In two individuals of the same age and sex the sulci and convolutions are never precisely alike. (2) The relations of the convolutions and sulci to the surface vary in different individuals. (3) That as the surface area of the scalp and outer aspect of the skull are greater than the surface area of the brain, and as the convexities do not tally, lines drawn on the scalp or skull cannot always correspond precisely to cerebral convolutions or sulci. It results from the above that when a definite area of the surface is said to correspond accurately in any individual to a definite area of the brain surface, this result has been correlated from many examinations; and that as surface-markings, shape, and processes of skull and arrangement of surface are all liable to variations in different individuals, the surgeon must allow for these variations by removing more than that definite area of skull which is said to correspond exactly to that part of the brain which he desires to expose.

A. **Relation of the brain as a whole to the skull** (figs. 1089, 1091).—To trace *the lower level of each cerebral hemisphere* on the skull, the chalk would start from the lower part of the glabella; thence the line representing the lower borders of the frontal lobe pursues a course, slightly curved upward, about 0.8 cm. ($\frac{1}{3}$ in.) above the supraorbital margin; next, crossing the temporal crest about 1.2 cm. ($\frac{1}{2}$ in) above the zygomatic (external angular) process, it passes not quite horizontally but descending slightly to a point in the temporal fossa just below the tip of the great wing of the sphenoid (pterion), 2.5 cm. (1 in.) behind the zygomatic process. From this point the line of the level of the brain, now convex forward and corresponding to the anterior extremity of the temporal lobe, would dip down, still within the great wing of the sphenoid, to about the centre of the zygoma. Thence the line of the lower border of the temporal lobe would travel along the upper border of this process about 6 mm. ($\frac{1}{4}$ in.) above the roof of the external auditory meatus (fig. 1089), and thence just above the base of the mastoid and the posterior inferior angle of the parietal, and so along the linea nuchæ suprema, and corresponding to the tentorium and horizontal part of the transverse (lateral) sinus, to the external occipital protuberance.

The **upper margin of each hemisphere** would be represented by a line drawn from just below the glabella, sufficiently to one side of the middle line to allow for the falx and superior sagittal sinus, to one immediately above the superior external occipital protuberance and inion.

B. **Relation of the chief fissures and convolutions to the skull.** C. **Localisation of the chief sulci and gyri.** These headings will be taken together.

It will be well first to indicate the position of the chief **sutures** which mark off the parietal bone, under which lies that part of the brain which is most important to the surgeon—the motor area. The upper limit of the bone will be indicated by the line already spoken of as giving the upper margin of the hemisphere—the **sagittal line,** or **Sagittal suture.** The anterior limit of the parietal bone, formed

FIG. 1089.—THE OUTLINE OF THE BRAIN AND ITS FISSURES IN RELATION TO THE SUTURES OF THE SKULL. (Cunningham.)

S.M. Supraciliary margin of the cerebrum. I.L.M. Infero-lateral margin of the cerebrum. L.S. Position of highest part of the arch of the transverse sinus. R. Central sulcus (Fissure of Rolando). S¹. Anterior horizontal limb of lateral fissure. S². Anterior ascending limb of lateral fissure. S³. Posterior horizontal limb of lateral fissure. P.B. by the **coronal suture,** may be traced thus: The point where it leaves the sagittal suture (the bregma) will be found by drawing a line from a point just in front of the external auditory meatus (the pre-auricular point) (fig. 1085) straight upward on to the vertex; from this point a line drawn downward and forward to the middle of the zygomatic arch would indicate that of the coronal suture. Under this suture lie the posterior extremities of the three frontal convolutions; for the frontal lobe lies not only under the frontal bone, but extends backward under the anterior part of the parietal, the central sulcus (fissure of Rolando), which separates the frontal from the parietal lobe, lying from 3.7 to 5 cm. ($1\frac{1}{2}$ to 2 in.) behind the coronal suture at its upper extremity and about 2.5 cm. (1 in.) at its lower.

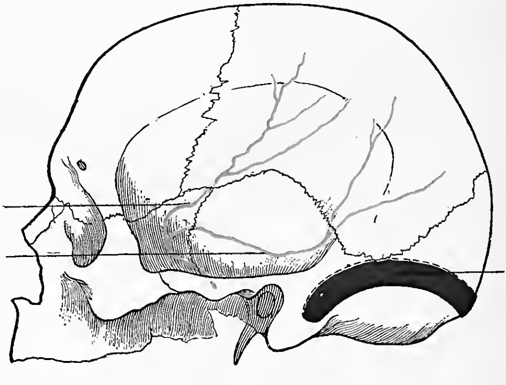
The squamoso-parietal suture, which marks the lower border of the anterior two-thirds of the parietal bone, is not so easy to define, owing to the irregularity and variations of its curve. Its highest point is usually 4.3 cm. ($1\frac{3}{4}$ in.) above the zygoma.

The lambdoid suture, which forms the posterior boundary of the parietal bone, will be marked out by a line which starts from a point (lambda) about 6.2 cm. ($2\frac{1}{2}$ in.) above the external occipital protuberance, and runs downward and forward to a point on a level with the zygoma, 3.7 cm. ($1\frac{1}{2}$ in.) behind and 1.2 cm. ($\frac{1}{2}$ in.) above the centre of the meatus.

The position of the chief sulci will now be given:—

Lateral (Sylvian) fissure (fig. 1089).—The point of appearance of this, on the outer side of the brain, practically corresponds to the pterion (p. 1332, fig. 1085)—a point which lies in the temporal fossa, about 3.7 cm. ($1\frac{1}{2}$ in.) behind the zygomatic process and about the same distance above the zygoma. From this point the lateral fissure, which here separates the frontal and parietal from the temporal lobe, runs backward and upward, ascending gently, at first in the line of the squamo-parietal suture, then crossing this suture about its centre and thence, ascending more rapidly, it climbs up to the temporal ridge, to end 1.8 cm. ($\frac{3}{4}$ in.) below the parietal eminence. Its termination is surrounded by the supramarginal convolution, to which the parietal eminence corresponds with sufficient accuracy. Such being the surface-marking of the chief or posterior horizontal limb of the lateral fissure (s^3, fig. 1089), it remains to indicate briefly the two shorter limbs which bound the inferior frontal convolution, which, on the left side, contains the centre for speech (Broca's convolution), and corresponds to a point lying three fingers' breadth vertically above the centre of the zygomatic arch. (Stiles.) Of these, the anterior horizontal (s^1, fig. 1089) runs forward across the termination of the coronal, just above the line of the spheno-parietal suture. The ascending limb (s^2, fig. 1089) runs upward for about

Fig. 1090.—Lateral View of the Skull, Showing the Topography of the Middle Meningeal Artery and the Transverse Sinus.



2.5 cm. (1 in.) just behind the termination of the coronal suture, or 5 cm. (2 in.) behind the zygomatic process.

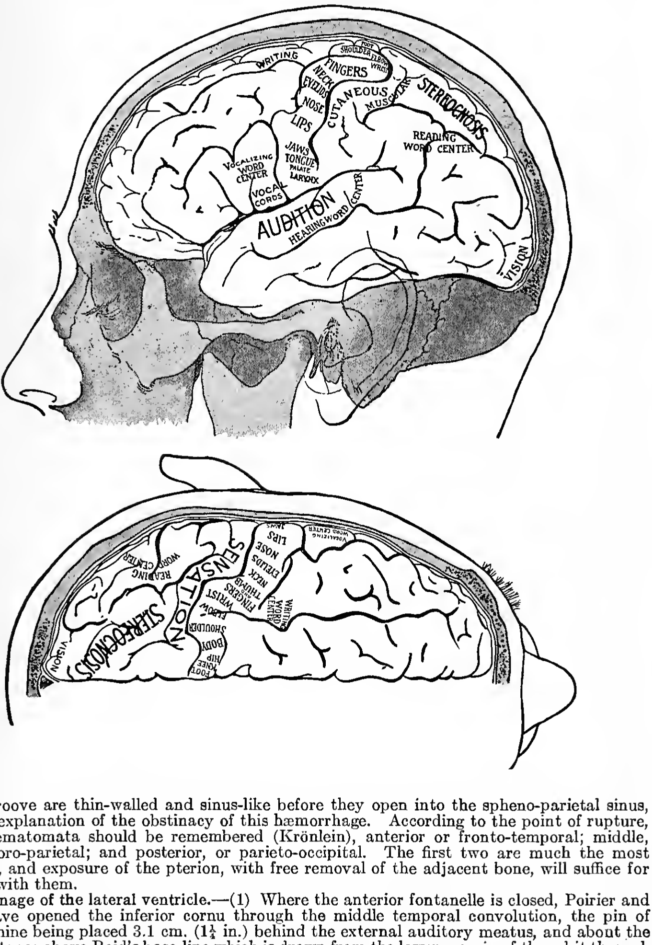
The central sulcus (fissure of Rolando).—This most important fissure, in front of which, in the precentral convolution of the frontal lobe, lie the motor centres for the opposite side of the body, is situated under the parietal bone. It may be marked out with sufficient precision in the following way (Thane): The sagittal line, from glabella to external occipital protuberance, is bisected, and a point 1.2 cm. ($\frac{1}{2}$ in.) behind the centre represents the **superior Rolandic point.** From this point a line drawn downward and forward 9 cm. ($3\frac{3}{4}$ in.) long, at an angle of $67\frac{1}{2}°$ with the sagittal line (i. e., $\frac{3}{4}$ of a right angle) will represent the central sulcus. The lower extremity of this line is known as the **inferior Rolandic point.**

This method is open to the objection that it only applies to the average adult skull, and not to skulls of all sizes. To obviate this difficulty the method of Krönlein may be employed in addition (fig. 1085). A base line BL is drawn through the lower border of the orbit and the upper border of the external acustic meatus. Parallel to this an upper horizontal line UH is marked out at the level of the upper margin of the orbit. Three lines vertical to the base line are now drawn, (1) at the posterior border of the mastoid process MR_1 (2) through the condyle of the lower jaw (CR_2), and (3) from the mid-point of the zygoma (ZS). The point R_1, where the first vertical joins the sagittal suture is the superior Rolandic point. The point S where the third vertical ZS cuts the line UH marks the junction of the three limbs of the lateral fissure. A line joining R_1 and S will cut the second vertical CR_2 at the inferior Rolandic point, R_2.

The posterior limb of the lateral fissure also may be represented by a line bisecting the angle R_1SH and ending behind at the point S^1 where it cuts the vertical MR_1.

Some further *points in the surgical anatomy of the cranium* must be referred to:—*The middle meningeal* artery. This vessel, entering the middle fossa by the foramen spinosum, grooves the great wing of the sphenoid and divides into two branches. The anterior grooves the anterior inferior angle of the parietal bone, and is then continued upward and slightly backward between the coronal suture and central sulcus (fig. 1090), almost to the vertex; the posterior branch takes a lower level, running backward under the squamous bone to supply the parietal and anterior part of the occipital bones. If a skull, bisected antero-posteriorly, be held up to the light, it will be seen how thin are the bones over the chief branches of this vessel, thus accounting for the slight violence sometimes sufficient to rupture it. The groove it occupies in the parietal is sometimes converted into a canal. A wounded artery retracting here may be very difficult to secure. The veins which accompany the artery and which lie lateral to it

Fig. 1091.—Cerebral Topography and Localization. (Cushing, from Keen's Surgery.)



in the groove are thin-walled and sinus-like before they open into the spheno-parietal sinus, another explanation of the obstinacy of this hæmorrhage. According to the point of rupture, three hæmatomata should be remembered (Krönlein), anterior or fronto-temporal; middle, or temporo-parietal; and posterior, or parieto-occipital. The first two are much the most frequent, and exposure of the pterion, with free removal of the adjacent bone, will suffice for dealing with them.

Drainage of the lateral ventricle.—(1) Where the anterior fontanelle is closed, Poirier and Keen have opened the inferior cornu through the middle temporal convolution, the pin of the trephine being placed 3.1 cm. ($1\frac{1}{4}$ in.) behind the external auditory meatus, and about the same distance above Reid's base-line which is drawn from the lower margin of the orbit through the mid-point of the external auditory meatus. The needle should here be directed to a point about 5 cm. (2 in.) above the opposite ear. (2) Kocher's point for draining the lateral ventricle is taken over the frontal lobe 2.5 cm. from the median line and 3 cm. in front of the upper Rolandic point. The needle is passed downward and a little backward to a depth of 4 or 5 cm.

Up to this point the **outside** of the cranium has been mainly considered; it remains to draw attention to some of *the chief points in the surgical anatomy* of the **interior**, especially of the **base**. **The three** fossæ are of paramount importance in fracture. In the **anterior fossa** the delicacy of parts of the floor, the connection of this with the nose and orbit, and the exact adaptation of its irregular surface to that of the frontal lobes, no 'water-bed' intervening, are the chief points. Thus the slightness of a fatal fissure, the frequent presence of bruising after a blow perhaps on the occiput, which has been considered to have caused only concussion, the characteristic palpebral hæmorrhage, and the infection of a fracture here are all explained, together with the possibility and gravity of a fracture here from a severe blow on the nose. In the **middle fossa** the frequency of fractures is explained by the facts that while here, as in the other fossæ, a fracture often radiates down from the vertex, the overlying vault being a region often struck, the base is weakened by numerous foramina and fissures. Further, the resisting power of the petrous bone must be lessened by the cavities for the internal ear, the carotid, and, to a less degree, by the jugular fossa. For fluids to escape through the external meatus, the dura, the prolongation of the arachnoid into the internal meatus, the membrani tympani, and probably the internal ear, must all be injured. The presence of the middle meningeal artery (fig. 1090) and the cavernous sinus in this fossa must also be remembered, especially in such operations as that on the Gasserian ganglion. **Posterior fossa**: It is not sufficiently recognised that fractures here are, owing to the anatomy of the parts, in some respects the most important of all. It is here that a small fissure-fracture, ultimately fatal, with severe occipital and frontal bruising and some intradural hæmorrhage, has been so often overlooked, especially in the drunken. This is explained by the supposed strength of the bone, this being really very thin in places, by the thickness of the soft parts, and the abundance of hair. Further, there is no very apparent escape of cerebral contents as in the anterior and middle fossæ. Blood, etc., may trickle into the pharynx far back, or a deep-seated ecchymosis coming up after two days, under the muscles about the mastoid process, may call attention to the damage within.

Dura mater.—The outer layer of this membrane acts as a periosteum, by bringing blood-vessels to the bone while the inner layer supports the brain. The influence of its partitions and its damping effect on vibrations is great in blows on the head. Its varying adhesions, according to site and age, must be remembered. Thus while it is intimately connected over the base with its adhesions to the different foramina, it is more loosely connected with the vault, as is shown in middle meningeal hæmorrhage. In early and later life the closeness of its connection with the bones is also more marked. It is united to the inter-sutural membranes.

Finally, the existence of **the cerebro-spinal fluid** with its power of lessening the evil of vibrations and its aid in regulating intra-cranial pressure, must be borne in mind. The chief collections, in which the subarachnoid meshwork is almost absent, are met with in front and behind the medulla. That in front, also lying under the pons, Hilton's 'water-bed,' sends a prolongation forward to the optic chiasma, but does not extend under the frontal or temporal lobes. The collection behind lies between the medulla and under surface of the cerebellum. Here, by the foramen of Magendie, the intra-ventricular cavities communicate with the sub-arachnoid space of the spinal cord.

THE HYPOPHYSIS CEREBRI

The **hypophysis (pituitary body)** which has now become of great clinical importance, consists of a pars anterior and pars intermedia derived from the buccal ectoderm, and a posterior pars nervosa formed by a downgrowth from the floor of the third ventricle. The gland lies in the fossa hypophyseos of the sphenoid bone, and an enlargement of it, apart from general skeletal and nutritional effect due to anomalies of its internal secretions, will cause pressure on the cavernous sinus on each side, and on the optic chiasma above. It will also expand the fôssa hypophyseos, pushing down its floor at the expense of the sphenoidal air sinus. Such enlargements may be detected by lateral radiograms. The normal size of the adult hypophyseal fossa (fig. 1097) is 10–12 mm. from before backward and 8 mm. from above downward (Keith).

The hypophysis may be exposed surgically either by turning the nose to one side, and removing the upper part of the septum and floor of the sphenoidal sinus, or by Cushing's method, in which a sublabial incision is made in the vestibule of the mouth, and through it the mucosa is then separated from each side of the nasal septum back to the sphenoidal sinus. A strip of septum is removed, and also the floor of the sphenoidal sinus, after which the hypophyseal fossa is opened and the gland exposed (fig. 1097).*

THE FACE

The topics included under this heading are the arteries, parotid region, nerves, mandible and maxilla, orbit, mouth, palate and nose.

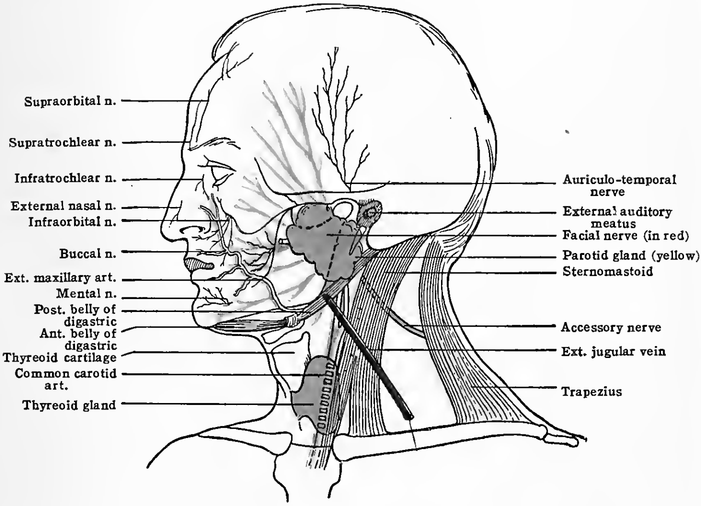
The outline of the different bones—nasal, upper and lower jaws, zygomatic

* H. Cushing. The Pituitary Body and its Disorders, 1912.

and zygoma—can be readily traced. The last mentioned and the glabella are alluded to on pp. 1331 and 1332; and the canine fossa should be identified as one of the antral routes. The delicacy, laxity, and vascularity of the skin are of great importance in all operations, while the abundance of large gland orifices accounts for the frequency of lupus here.

Arteries.—The **supraorbital artery** can be felt beating just above its notch (junction of medial with lateral two-thirds of supraorbital margin); the little **frontal artery** is of importance, as it nourishes the flap when a new nose is taken from the forehead; the **superficial temporal,** accompanied by the auriculo-temporal nerve, can be felt where it crosses the root of the zygoma just in front of the tragus, its anterior branch about 3.1 cm. ($1\frac{1}{4}$ in.) above and behind the zygomatic process of the frontal; the **occipital,** accompanied by the great occipital nerve (fig. 450), pulsates to the medial side of the centre of a line drawn from the occipital protuberance to the mastoid process; the **posterior auricular,** rather deeply, between the auricle and the mastoid process. The **external carotid** lies behind the ascending

Fig. 1092.—Surface Relations of Vessels and Nerves in Lateral View of the Face and Neck.

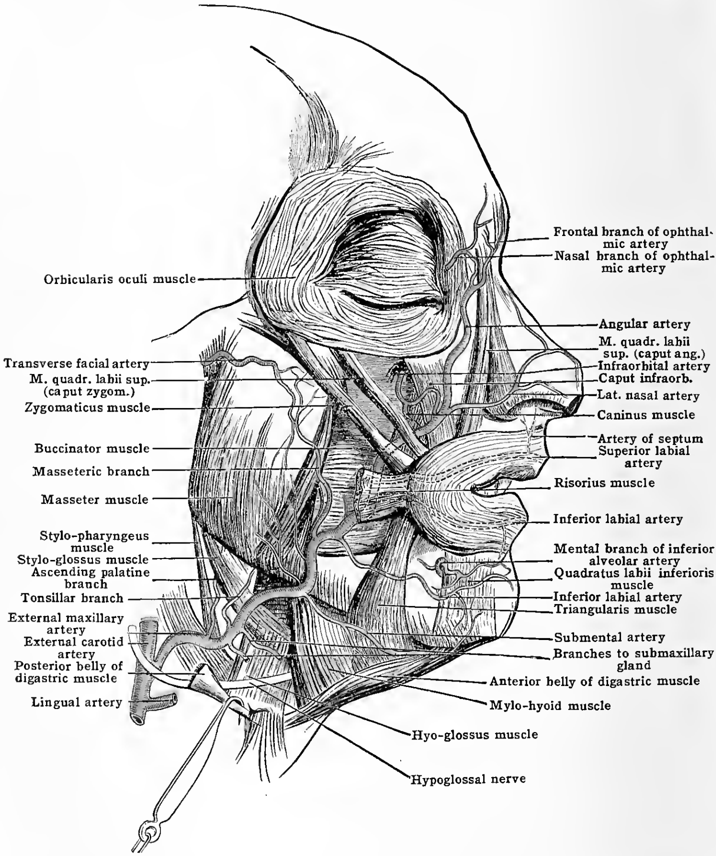


ramus of the jaw. The **external maxillary** (fig. 1093) crosses the jaw just in front of the masseter; if divided, both ends must be secured here. It can be felt again a little behind the angle of the mouth, just beneath the mucous membrane (it here gives off the labial branches, which can also be felt, lying deeply, if the lip is taken between the finger and thumb); and again by the side of the nose, as it runs up to the angulusoculi. The small angular branch is, from its position, always troublesome to secure. To trace the course of the **external maxillary** artery a line should be drawn from a point a little above and lateral to the tip of the great cornu of the hyoid to the lower part of the anterior border of the masseter, and thence to one lateral to and above the angle of the mouth, and so onward, lateral to the angle of the nose, up to the medial angle. The **anterior facial vein** takes a straight course behind the tortuous external maxillary artery. The absence of valves and its communication by the angular and ophthalmic veins with the cavernous sinus, and, by the deep facial, with the pterygoid plexus, are of grave importance in infective thrombosis. The external jugular vein will be mentioned later.

Parotid region.—A line drawn from the lower border of the meatus to a point midway between the nose and upper lip gives the level of the **parotid duct,** which opens into the mouth opposite the second molar tooth. The level of the duct, somewhat inconstant, would be usually about a finger's breadth below the zygoma. It is accompanied by the transverse facial artery above, and the infraorbital branch of the facial nerve below.

The sheath of the parotid, continuous with those of the masseter and sterno-mastoid, is strong enough to cause most exquisitely painful tension when inflammation of the gland is present, and, together with the presence of deep processes of the gland in connection with the

Fig. 1093.—Scheme of the External Maxillary (Facial) Artery. (Walsham.)



mandibular (glenoid) cavity and styloid process, to explain the deep burrowing of pus which may take place into the pharynx and pterygoid region. The relation of the capsule to growths, innocent or malignant, of the parotid is also important (See figs. 865, 1092).

The parotid region would be thus mapped out (fig. 1096). *Above* by the posterior two-thirds of the zygoma; *below*, by a line corresponding to the posterior belly of the digastric (fig. 1096); *behind*, are the external auditory meatus, mastoid, and sterno-mastoid. *In front* the gland and socia parotidis overlap the posterior part of the masseter, to a variable degree (fig. 1096).

Sensory nerves.—The cutaneous nerve areas of the face are shown in fig. 774. The **supraorbital** nerve, the main sensory branch of the ophthalmic, emerges from the orbit with its companion artery through the notch (occasionally a foramen) at the junction of the medial third and lateral two-thirds of the supraorbital margin. A line drawn from the supraorbital notch downward across the interval between the bicuspid teeth will cross the **infraorbital foramen** from which emerges the **infraorbital nerve,** the main terminal division of the maxillary, at a point 1 cm. below the orbital margin. The mental foramen, the point of exit of the *mental nerve*, a branch of the inferior alveolar, is found on a prolongation of the same line midway between the upper and lower margins of the mandible in the adult. In the infant in whom the alveolar element of the jaw is relatively large, the mental foramen is nearer the lower margin, while in the edentulous jaw of old age it is found much nearer the upper margin.

In trephining to expose the inferior alveolar (dental) nerve, one of the common seats of neuralgia and one in which a peripheral operation is justified from the results, the ascending ramus is opened midway between its anterior and posterior borders, on a level with the last molar.

The **semilunar ganglion** lies at a depth of 5.5–6 cm. ($2\frac{1}{4}$ in.) under the eminentia articularis at the base of the zygoma. In exposing it for the purpose of excision for intractable neuralgia the following structures are encountered: (1) Skin and superficial fascia with branches of the superficial temporal artery; (2) temporal fascia and muscle with deep temporal vessels; (3) squamous bone and great wing of sphenoid, which are trephined, the floor of the middle fossa being gouged away; (4) middle meningeal vessels and dura mater. By elevating the dura mater and superimposed temporal lobe, and securing the middle meningeal artery, the ganglion is exposed, lying in a separate compartment [cavum Meckelii] of the dura, which contains cerebrospinal fluid. The motor nerve of the muscles of mastication lies on the lower and medial aspect of the ganglion, and should not be divided.

Injection of the mandibular nerve with alcohol, by means of a long stout hypodermic needle is practised in cases of intractable neuralgia as an alternative to excision of the semilunar ganglion. A vertical line is drawn on the cheek downward from the junction of the posterior and middle thirds of the zygomatic arch, and the needle is entered on this line at a point 1.5 cm. from the lower border of the zygoma. It is directed upward and medially so as to pass through the lowest part of the mandibular notch. If the mouth is opened the notch is depressed and more room gained. The needle impinges first against the inferior surface of the great wing of the sphenoid bone, and when the point is lowered a little it engages in the foramen ovale at a depth of 4–4.5 cm. In most cases the needle can be passed through the foramen ovale into the semilunar ganglion. (Harris.)*

The **maxillary nerve** may be injected by passing a needle along the floor of the orbit from its infero-lateral angle in a direction backward and slightly medially to the foramen rotundum which lies 4.5 cm. from the surface.

Facial nerve.—In the petrous bone the course of this nerve is first outward and forward, then, having entered the facial canal, backward and downward along the medial wall of the tympanum, above the fenestra ovalis. Emerging from the stylo-mastoid foramen the nerve takes first the line of the posterior belly of the digastric, running forward and a little downward from the anterior border of the mastoid where this meets the auricle. (Godlee.) Entering at once the posterior part of the parotid, it crosses the neck of the mandible at the level of the lower border of the tragus.

The frequent paralysis of this nerve may thus depend upon—(1) cerebral causes; (2) disease of or injury to the petrous portion; (3) affections after its exit—Bell's paralysis. A diagnosis may be arrived at by attention to the following. In *cerebral disease* the lower part of the face is chiefly affected, the eyelids usually escaping. In all the other forms the whole side of the face is paralysed. Hemiplegia of the opposite side of the body and paralysis of the sixth nerve are usually present. In *petrous paralysis*, owing to involvement of the chorda tympani, there may be interference with the saliva and taste, affecting especially the anterior part of the tongue. The auditory nerve may also be affected. Here and in (3) there will be a history of disease or injury. In complete paralysis the smooth side of the face and forehead, the absence of power of expression, to frown, to blow, or whistle, the open eyelids and epiphora, and subsequent liability to mischief in the cornea, the dropping of the angle of the mouth and dribbling of saliva, the interference with mastication from paralysis of the buccinator, are the chief points.

Mandible.—Dislocation of the temporo-mandibular joint is referred to on p. 217. In the usual **dislocation,** from muscular action, the jaw is suddenly brought forward against the anterior part of the capsule, which tends, by the action of the depressors, to give way; the elevators then pull up the mandible, a sequence that must be remembered in reduction. In the commonest **fracture** of

* Lancet, Jan. 23, 1912.

the mandible—unilateral, near the mental foramen—the larger anterior fragment will be pulled by the depressors downward and medially, the smaller posterior one upward and usually lateral to the other fragment.

Maxilla.—The boundaries of the **maxillary sinus (antrum)** are of much importance. The base of this irregularly pyramidal cavity corresponds to the middle and inferior meatuses on the lateral wall of the nose; toward the upper and back part is the opening into the middle meatus. The apex runs laterally toward the zygomatic process. The roof is formed by the orbital plate with the infraorbital nerve and vessels anteriorly; the floor by the junction of the alveolar arch, carrying the first molars (and often the bicuspids), with the hard palate. It may be pierced by the roots of the second bicuspid or first and second molar teeth. Anteriorly, the antrum is bounded by the canine fossa; posteriorly it is in relation with the zygomatic fossa. The cavity, present at birth, increases gradually up to the twelfth year.

The chief paths of infection are through the teeth (especially the first and second molar), the nose, and frontal sinus. The obstinacy of inflammation here is explained by the site of the opening, high up on the medial wall, and thus inadequate drainage, by the imperfectly multilocular cavity of the interior and its rigid walls. The chief sites for *opening the antrum* are—(*a*) through the sockets of the first or second molars; (*b*) through the canine fossa, after the reflection of mucous membrane has been detached, midway between the roots of the teeth and the infraorbital foramen (this path gives more room); (*c*) through the inferior meatus of the nose.

THE ORBIT AND EYE

The **bony orbit** is a pyramidal fossa with its **base** at the orbital margin and its **apex** at the optic foramen. The medial walls of the two orbits are approximately parallel, but the lateral walls diverge as they are traced forward and lie at right angles to each other. The thin **floor** which is formed mainly by the maxilla and corresponds to the roof of the maxillary sinus, is readily destroyed by growths extending up from the sinus and in the process pressure on the infraorbital nerve is apt to cause pain referred to the cheek. The **roof** formed by the orbital plate of the frontal bone is also thin, and foreign bodies thrust into the orbit may perforate it and enter the frontal lobe of the cerebrum. The **medial wall** is chiefly constituted by the lacrimal and lamina papyracea of the ethmoid, both very thin bones. This wall is readily destroyed by malignant growths of the nose.

Injuries of the medial wall such as may be associated with fractures of the nose bring the ethmoidal air cells into communication with the cellular tissue of the orbit. The latter may thus be distended with air on attempting to blow the nose.

The **lateral wall** is formed in its anterior third by the zygomatic bone, which separates the orbit from the zygomatic fossa. The posterior two-thirds formed by the sphenoid bone separate the orbit from the temporal lobe of the brain in the middle cranial fossa. The orbit communicates with the cranium by the optic foramen, which transmits the optic nerve and ophthalmic artery and the superior orbital fissure through which pass all the other vessels and nerves of the orbit.

In cases of fracture of the base of the skull involving the anterior clinoid process, a traumatic communication (arterio-venous aneurysm) may be formed between the internal carotid artery and cavernous sinus, behind the apex of the orbit, giving rise to pulsating exophthalmos.

The **orbital margin** is larger in the transverse than in the vertical direction, and consequently there is more space on either side than above and below between it and the eyeball which is nearly spherical. The eyeball lies nearer to the medial than to the lateral margin and hence foreign bodies more commonly penetrate the orbit to the lateral side of the eye.

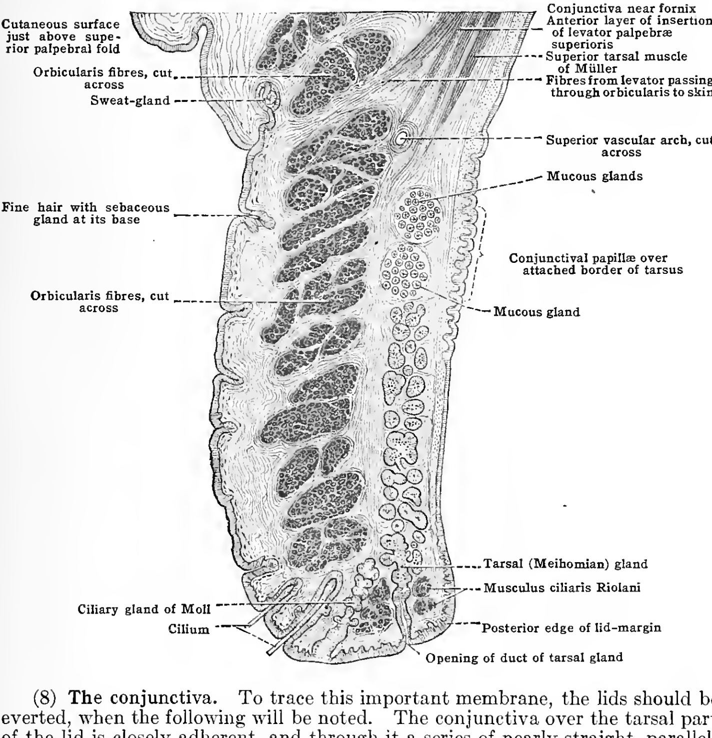
Behind the **fascia bulbi,** the eyeball rests on a mass of soft loose orbital fat in which foreign bodies may be hidden for a considerable time.

The structure of the eyelids.—The different layers are of much practical importance. (1) The **skin** is delicate and fatless, and contains pigment, the object of this being to protect the eye from bright light. It helps to explain the 'dark circles' of later life. (2) **Areolar tissue.** Owing to its looseness and delicacy, this is very liable to infiltration, as in œdema and erysipelas. (3)

Orbicularis. Paralysis of this, the palpebral portion, leads to epiphora, the puncta being no longer kept in their normal backward direction against the conjunctiva. (4) **Palpebral fascia,** reaching from the orbit to the tarsal cartilage. This is usually strong enough to prevent hæmorrhage, due to fractured base of skull, becoming subcutaneous. (5) **Levator palpebræ.** (6) **Tarsal plate;** in reality, densely felted fibrous tissue. (7) **Tarsal** (Meibomian) **glands, lashes, and sebaceous follicles.**

Localised inflammation starting in any of these last three structures, especially the last, will cause a 'stye.' The frequency with which the lid-border is the seat of that most troublesome chronic inflammation, blepharitis, and its result, 'blear eye,' is explained by these anatomical points. Its circulation is terminal and slow; half skin and half mucous membrane, it is moister and more liable to local irritation than the skin; while its numerous glands readily participate in any inflammation.

FIG. 1094.—SAGITTAL SECTION THROUGH THE UPPER EYELID. (After Waldeyer and Fuchs.)



(8) **The conjunctiva.** To trace this important membrane, the lids should be everted, when the following will be noted. The conjunctiva over the tarsal part of the lid is closely adherent, and through it a series of nearly straight, parallel, light yellow lines and granules, the tarsal glands, can be seen. Owing to their position here (fig. 1094) and to avoid scarring, a tarsal cyst is always opened on its conjunctival surface.

Beyond the tarsi, the palpebral conjunctiva is thicker and freely movable owing to the abundant lax submucous tissue. Underlying vessels are visible here. Leaving the eyelid the conjunctiva is reflected onto the eyeball at the **fornix.** Into the lateral part of the upper fornix open the ducts of the lacrimal gland. The bulbar conjunctiva is continued over the front of the eyeball to the corneal margin. It is thin and contains fine vessels which are distinguished from subjacent episcleral vessels by the fact that they move with the conjunctiva.

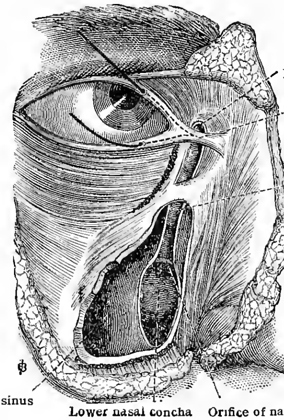
These **conjunctival vessels**, derived from the lacrimal and palpebral arteries, become very visible in conjunctivitis. In deep inflammation affecting the iris and ciliary body, the episcleral branches of the anterior ciliary arteries (which are derived from the muscular and lacrimal arteries) become engorged and are visible as a pink circumcorneal zone of congestion, deeply situated under the conjunctiva. These branches take a large share in the nutrition of the cornea, and are responsible for the vascularity of *pannus* and the '*salmon patches*' of interstitial keratitis.

The **conjunctival nerves** for the upper lid and bulbar part of the membrane, and the nerves to the cornea, are supplied by the ophthalmic division of the trigeminal. The maxillary division of this nerve supplies the lower palpebral conjunctiva.

The differing structure of the palpebral and ocular portions has important bearings. Thus the palpebral conjunctiva is thick, highly vascular and sensitive. To this vascularity we owe the chemosis, or hot, red, tense swelling of purulent ophthalmia. The exquisite suffering of the same disease, or that caused by a foreign body, is explained by the numerous nerve-papillæ and end-bulbs. To the thickness and abundance of the connective tissue are due the contraction and permanent thickening which may occur in granular lids. The so-called granulations, met with in this disease on the palpebral conjunctiva, are really little nodules of hypertrophied lymphoid follicles, or mucous glands, which abound here.

Immediately under the bulbar conjunctiva, between it and the sclerotic, lies the anterior part of the **fascia bulbi** (of Tenon). This fibrous membrane forms a sheath for the posterior

Fig. 1095.—The Lacrimal Apparatus and Naso-lacrimal Duct. (Bellamy.)
(Bristles are introduced into the puncta lacrimalia.)



five-sixths of the eyeball, and is intimately connected with the sheaths of the extrinsic muscles and through the **check ligaments** with the orbital walls. Together with the conjunctiva it must be opened in the operation of tenotomy for strabismus, and after division of a rectus tendon the muscle retains some control over the eye through its connection with the fascia bulbi. In enucleation of the eyeball both conjunctiva and fascia bulbi are divided around the cornea, where they are intimately blended. In removal of the upper jaw the attachment of the suspensory ligament of this fascia must always be left if possible, for otherwise the eyeball will tend to fall forward and the cornea suffer from its exposure (Lockwood). Finally the cavity between the two layers of the capsule is continuous with the extensions of the cerebral membranes along the optic nerve, i. e., with the subarachnoid space.

For an account of the intrinsic and extrinsic muscles of the eye the reader is referred to the section on the Eye. Reference may be made here, however, to the part played by certain fibres of the **cervical sympathetic** system. Emerging from the cord at the first and second thoracic segments, the communicating fibres pass up the sympathetic chain in the neck to cell stations in the superior cervical ganglion. Thence continuing onward through the carotid canal and superior orbital fissure, they supply (1) the dilator muscle of the iris, (2) the unstriped muscle element in the eyelids, and (3) smooth muscle fibres, decribed by Sappey, in the check ligaments and fascia bulbi. Paralysis of the cervical sympathetic nerve in the neck, usually in its lowest part, by trauma or the pressure of a malignant growth, causes therefore (1) narrowing of the pupil, (2) narrowing of the palpebral fissure (pseudo-ptosis), and (3) enophthalmos.

The **lacrimal gland** lies in a hollow at the supero-lateral angle of the orbit, protected by the zygomatic process of the frontal bone. It is not palpable normally. Its lower or palpebral portion rests on the lateral third of the fornix conjunctivæ, into which the numerous ducts open, and it may be seen through the conjunctiva on everting and raising the upper lid.

The position of the lacrimal puncta should be noted; owing to their backward direction, the lids must be previously everted. The puncta are kept open by a minute fibrous ring.

Each is situated on a minute papilla at the junction of the medial and straight third of the lid with the lateral curved two-thirds. Close to the medial angle, in addition to the puncta and papillæ, should be noted the caruncula lacrimalis, with its delicate hairs, and the plica semilunaris, which corresponds to the third eyelid of certain birds.

The **lacrimal sac** is a most important part of the lacrimal apparatus, from its disfiguring diseases; it lies in a bony groove, between the nasal process of the maxilla and the lacrimal bone. The medial palpebral ligament crosses it a little above its centre (fig. 1095). Thus two-thirds of the sac are below the ligament, and in suppuration the opening is made below it also. The angular artery ascends on the nasal side of the sac.

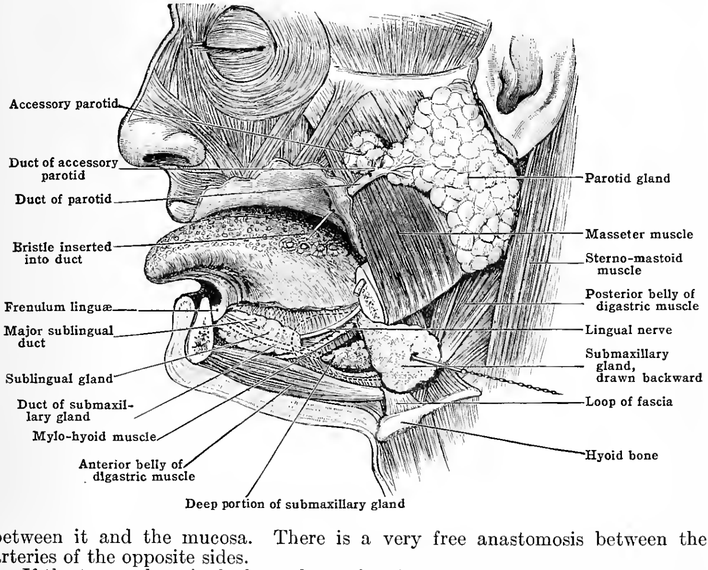
The **manipulation of a probe along the lacrimal passages** should thus be practised:—the lower lid being drawn laterally and downward by the thumb, the probe is passed vertically into the punctum, then turned horizontally and passed on till it reaches the medial wall of the sac. It is then rotated somewhat forward, raised vertically, and pushed gently along the duct downward, and a little lateralward and backward, till the floor of the nose is reached, the operator aiming, as it were, for the site of the first molar tooth. The *naso-lacrimal* duct extends from the lower end of the lacrimal sac to the inferior meatus of the nose and is about 1.2 cm ($\frac{1}{2}$ in.) in length.

If the eyes are opened naturally, the greatest part of the cornea, behind it the iris, with the pupil in the centre, on either side of the cornea some of the sclerotic, the semilunar fold, and caruncle can be seen.

THE MOUTH

The lips.—When the whole thickness of the lip is incised the labial artery will be found lying near the free margin, internal to the orbicularis muscle, and

Fig. 1096.—Side of the Face and Mouth Cavity, showing the Three Salivary Glansd.



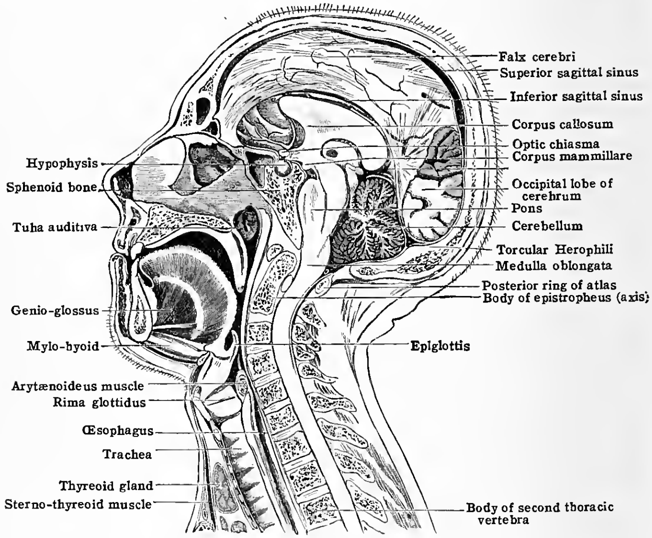
between it and the mucosa. There is a very free anastomosis between the arteries of the opposite sides.

If the tongue be raised, the under surface is seen to be smooth and devoid of papillæ. In the middle line is the **frenulum.** When division of this is really required in tongue-tie, the scissors should be kept close to the bone, in order to avoid the ranine vessels.

Of these, the veins can be seen just to one side; the arteries are close by, but deeper. Farther out are two more or less distinct fringed folds, the plicæ fimbriatæ, running from behind forward and, like the frenulum, disappearing before the tip. Between these and the frenulum are the small apical mucous glands of Nuhn or Blandin. Farther back, at the junction of the mucous membrane and the alveoli, are two other projections of the mucosa, the sublingual; under these are the sublingual glands, the ranine veins, and, more deeply, Wharton's duct and the termination of the lingual nerve. The majority of the ducts of the sublingual gland (Rivinian) open on the sublingual ridges. A single larger one, Bartholin's, opens with that of Wharton, or close to it, on either side of the frenulum (fig. 1096). Dilatation of one of the Rivinian ducts, more frequently dilatation of a muciparous gland—and, much more rarely, dilatation of Wharton's duct—constitutes a 'ranula.'

The **submaxillary gland** can be felt nearer the angle of the jaw, lying between its fossa and the mucous membrane, especially if pressure is made from outside. The attachment of the **genio-glossi** can be felt behind the symphysis: the division of the muscles allows the **tongue** to come well out of the mouth; but when both have to be divided, the tongue loses much of its steadiness, and may easily fall

Fig. 1097.—Sebtion of the Skull and Brain in thf Median Plane. (Braune.)



back over the larynx during the administration of the anæsthetic or, later on, in sleep. It should therefore be secured forward for a while with silk. For the same reason, in removal of one-half of the mandible, part of this muscular attachment should always be left, if possible.

Turning now to the dorsum of the tongue, this shows two distinct parts: one, the anterior two-thirds, *the buccal*, is rich in papillæ; the other, the posterior, *the pharyngeal*, contains abundant lymphoid follicles like the tonsil. This part possesses peculiar sensibility, as shown by movements of tongue and palate when a depressor is placed too far back. The two parts are separated by the V-shaped arrangement of the vallate papillæ, with the apex turned backward. Immediately behind the apical vallate papilla is a small pit, the foramen cæcum which represents the upper remains of the thyreoglossal tract, and may be the seat of lingual thyreoid growths. While the tongue is mainly a muscular organ, the fine fatty connective tissue in the septum and between the muscular bundles is the seat of that dangerous condition acute glossitis, and of gummatous infiltration. While the mouth is widely open, the pterygo-mandibular ligament can be seen and felt beneath the mucous membrane, behind the last molar tooth. Just below and in front of the lower attachment of this ligament the **lingual nerve** can be felt lying close to the bone below the last molar. The simplest and surest method of dividing the nerve here, to give relief from pain in incurable carcinoma of the tongue, is to draw the tongue out of the mouth and expose the nerve where it lies superficially under the mucous membrane thus made prominent between the side of the tongue and the gums, the centre of the incision being opposite to the last molar tooth. (Roser, Létiévant.) In cancer of the tongue pain is often referred up the auriculo-temporal nerve to the ear and side of head.

Behind the last molar tooth can be felt the **coronoid process,** and higher up, just behind and medial to the tooth, the **pterygoid hamulus of the sphenoid.** This process is a landmark to the site of the greater palatine foramen, which lies just in front of it, and which transmits the greater palatine branch of the descending palatine artery, together with the anterior palatine nerve. The vessel and nerve run forward in grooves on the lower surface of the palatine process of the maxilla, giving off anastomosing branches toward the middle line, and join at the incisive foramen with the nasopalatine artery.

Their position must be remembered in raising the flaps during the operation for closure of a cleft in the hard palate. To ensure the vitality of the flaps the incisions must be made lateral to the vascular arch, close to and parallel with the upper alveolus, and should not extend beyond a point opposite to and just medial to the last molar tooth, for fear of encroaching upon the posterior palatine canal.

When the teeth are clenched, there is still a space, communicating between the mouth and pharynx behind the molar teeth, which admits a medium-sized catheter. When a patient breathes deeply through the mouth and the head is thrown back, the soft palate is raised, the pillars (arches) separated; the uvula and fauces, with the anterior and posterior pillars, with their attachments, the tonsils, and the back of the pharynx are exposed.

This portion of the pharyngeal mucous membrane would lie over the lower part of the second and the upper part of the third cervical vertebræ, the anterior arch of the atlas corresponding to the level of the posterior nares, and the body of the epistropheus (axis) to the level of the soft palate (fig. 1097). If a finger be introduced past the soft palate to this part of the spine and turned upward and downward, it is possible, with the aid of an anæsthetic, to examine the upper four or five and, in children, six vertebræ, as far as the anterior surfaces of their bodies. 'The part of the column which is accessible to a straight instrument introduced through the mouth is very limited, extending, in the adult, from the lower border of the axis to the middle or lower part of the fourth cervical vertebra; in the child, owing to the small size of the face, it comprises the bodies of the axis and of the third cervical vertebra.' (Thane and Godlee, from Chipault.) The distance from the incisor teeth to the commencement of the œsophagus at the cricoid cartilage is 15 cm. (6 in.) in the adult, and the distance from the teeth to the cardiac orifice of the stomach is 48 to 50 cm. (16 or 17 in.).

The lymphatic drainage of the face, mouth, and tongue is given on pp. 712 and 715.

Tonsils.—The **relations of the tonsils** should be carefully examined. Thus, they are separated externally by the superior constrictor and pharyngeal aponeurosis from the oscending pharyngeal and internal carotid arteries. The latter vessel lies about 2.5 cm. (1 in.) behind and to the lateral side of the tonsil. When serious hæmorrhage follows operations here, it usually comes from one of the numerous tonsillar branches (fig. 448). The extent to which the tonsil is covered by the anterior pillar, how far it projects upward beneath the soft palate or downward into the pharynx, have all important bearings on the mode of removal. Its position corresponds to a point a little above and in front of the angle of the jaw. The lateral surface, enclosed by an imperfect capsule and separated from the superior constrictor by connective tissue, explains how an enlarged tonsil can be dragged medialward by a vulsellum, and enucleated after an incision in the mucous membrane around. It is in this connective tissue that severe infective inflammation, e. g., after scarlet fever or an imbedded pipe-stem, may set up hæmorrhage or spreading cellulitis, retro-pharyngeal or otherwise.

The **finger introduced downward at the back of the mouth,** especially if the parts are rendered in sensitive by local anæsthetics, feels the vallate papillæ, the lingual and laryngeal surfaces of the epiglottis, the arytæno-epiglottidean folds, with the cuneiform and corniculate cartilages. **If the finger be moved upward** behind the soft palate and turned upward to the base of the skull, and then forward, it will feel the choanæ (posterior nares), separated by the vomer. The other boundaries of these are, laterally, the medial pterygoid plate and palate bones; above, the basisphenoid; and below, the horizontal plate of the palate bone and the inferior nasal spine. Within each nostril would be felt the posterior ends of the two lower nasal conchæ (turbinate bones); above and behind is felt the basilar process of the skull, the vault of the pharynx, and the bodies of the upper cervical vertebræ (fig. 1097).

The **size of the choanæ,** in the bony skull 2.5 cm. (1 in.) vertically by 1.2 cm. ($\frac{1}{2}$ in.), and the presence of any adenoids, are especially to be noted. The **richness of the naso-pharynx in glandular structures,** its proneness to inflammation, and of this inflammation to spread to other parts,—e. g., the tympanum,—are well known. The finger should be familiar with the feel of adenoids—i. e., hypertrophied post-nasal lymphatic nodules—soft bodies of irregular shape blocking up the naso-pharynx. To make out how far this is the case, it is well to take the nasal septum as the starting-point.

Pharyngeal hypophyseal remnants.—In the naso-pharyngeal mucosa, a few millimetres behind the posterior border of the vomer, a group of glandular cells may be found on microscopical examination in all cases (Haberfeld), corresponding in histological appearance with the pars anterior of the hypophysis. These cells are a remnant of the primitive bud that grows toward the brain in front of the bucco-pharyngeal membrane to form the pars anterior of the hypophysis. In some cases of pituitary disorder they give rise to a palpable tumour in the naso-pharynx.

The palate.—Between the diverging pillars of the soft palate is the **isthmus faucium,** bounded above by the free margin of the palate, and below by the dorsum of the tongue. The space between the arches (pillars), glossopalatine and pharyngo-palatine, with attachments denoted by their names, shallow above, widens and deepens below. Of its lateral boundaries, the posterior pillars come nearer each other than the anterior. The coverings of the hard palate are chiefly mucous membrane, glands, and periosteum. These are intimately blended by fibrous septa, as in the superficial layers of scalp and palm of the hand. Hence the readiness with which necrosis takes place here.

Hare-lip and cleft palate.—Failure of union between the mesial nasal process and the maxillary process of the embryo gives rise to the deformity known as **hare-lip.**

The palate is developed from three primitive processes growing down from the basis cranii, viz., (1) the mesial nasal process forming the premaxilla which lies in front of the anterior palatine foramen and bears the four incisor teeth, (2) and (3) the maxillary process of either side. The slighter cases of failure to unite affect only the soft palate which is the last part to fuse. Complete alveolar cleft palate, which occurs combined with hare-lip and may be unilateral or bilateral, represents more serious non-union. In this condition the lateral incisor may be found either on the medial or on the lateral side of the cleft, which is explained by the fact that this tooth is developed in the groove between the two processes (Keith).

In paring the edges of a cleft soft palate, the following structures would be, successively, cut through:—(1) Oral mucous membrane; (2) submucous tissue, with vessels, nerves, and glands; (3) glosso-palatine muscle; (4) aponeurosis of tensor palati; (5) anterior fasciculus of pharyngo-palatine; (6) levator palati and uvular muscles; (7) posterior fasciculus of pharyngo-palatine; (8) submucous tissue, vessels, nerves, and glands; (9) posterior mucous membrane. The soft palate is thicker than it seems, the average in an adult being 6 mm. ($\frac{1}{4}$ in.). The muscles widening a cleft are the tensor and levator, while the superior constrictor closes it in swallowing. Of the *arteries* of the palate, from the external maxillary (facial), ascending pharyngeal, and internal maxillary, the largest is the descending palatine branch of the last. This emerges from the posterior palatine canal close to the inner side of the last molar tooth.

THE NOSE

On the face the outline of the nasal bones can be easily traced, and below them the lateral nasal cartilages, flat and also somewhat triangular. Below these are the greater alar cartilages, curved and so folded back that each forms a lateral and a medial plate. Of these, the medial meet below the septal cartilage to form the tip of the nose, while the lateral curve backward, and, together with dense masses of cellular tissue and fat and accessory cartilages, form the alæ.

With the speculum, especially if the head be thrown back and the tip of the nose drawn up, the lower part of the septum, floor of the nose, and greater portion of the inferior concha (turbinate bone) can be seen. On throwing the head further back, with a good light the lower margin of the middle concha can also be made out. This is much higher up and nearly on a level with the root of the nasal bone. The septum often deviates to one side. The mucous membrane over it is, in health, dull red in colour; that over the inferior concha is thicker. The anterior extremity of the latter bone is about 1.8 cm. ($\frac{3}{4}$ in.) behind the nasal orifice, while the opening of the naso-lacrimal duct is about 2.5 cm. (1 in.) behind and about 1.8 cm. ($\frac{3}{4}$ in.) above the floor, concealed by the anterior extremity of the inferior concha. The opening into the maxillary sinus (antrum) is situated in about the centre of the middle meatus and 2.5 cm. (1 in.) above the floor

The **olfactory area of the mucous membrane** extends over the highest concha (possibly also somewhat lower) and corresponding portions of the septum. The **respiratory portion** is more vascular and thicker, especially over the conchæ. It is firmly adherent to the periosteum and perichondrium. The veins, especially over the lower conchæ, form a dense plexus, closely resembling cavernous tissue.

This fact explains the severity of epistaxis, and, together with the drainage of blood into out-of-the-way veins, such as the spheno-palatine and ethmoidal,

Fig. 1098.—Section of the Nose, showing the Conchæ (Turbinate Bones) and Meatuses with the Openings in Dotted Outline.

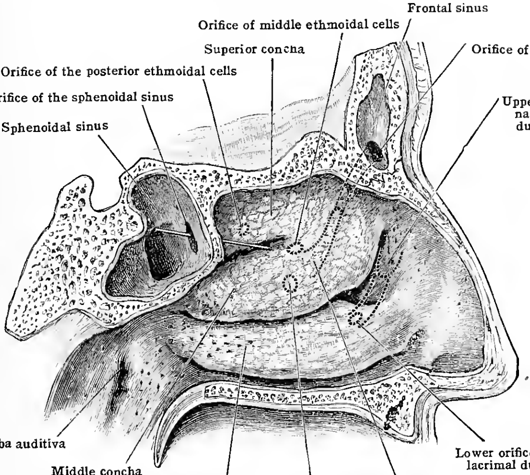


Fig. 1099.—Section showing Bony and Cartilaginous Septum.
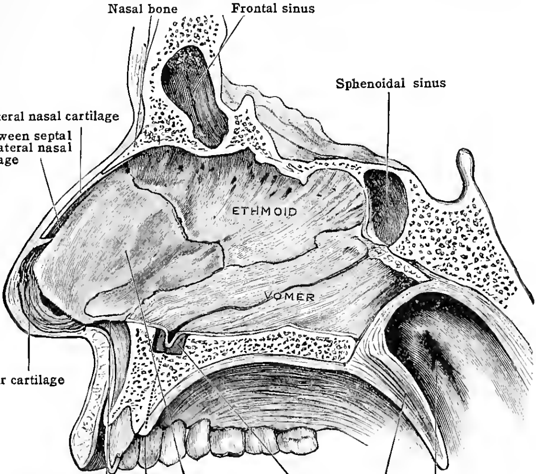
The dotted line indicates the course of the incisive (anterior palatine) canal.



accounts for the serious results which may follow on a firmly impacted and infected plug. The boundaries of the posterior nares have been given above.

About 1.2 cm. (½ in.) behind the posterior extremities of the inferior conchæ, just above the level of the hard palate (fig. 1097), on the side of the naso-pharynx, are the openings of the *tubæ auditivæ* (**Eustachian tubes**). Oval in shape, these are bounded above and behind by the prominence of the cartilage, which is wanting below, thus facilitating the entry of a catheter. The lower part of the tube contains in early life lymphoid tissue; enlargement of this explains the deafness in certain cases of adenoids. At the upper part of the naso-pharynx, on the posterior wall, extending down laterally as far as the tubæ auditivæ, is the collection of lymphoid tissue known as the **pharyngeal tonsil,** which when hypertrophied, plays a large part in 'naso-pharyngeal adenoids.' From the periosteum of the basi-sphenoid and basi-occipital arise naso-pharyngeal fibromata.

Nasal septum.—The structure of the skeletal element of the septum, which consists of the septal cartilage, the vertical plate of the ethmoid and the vomer, is shown in fig. 1099. Slight deviations of the septum to one side are common in adults, and involve mainly the cartilage and the ethmoid bone, the vomer being but little affected as a rule.

The convexity is most commonly on the right side, and occlusion of the nares on that side with unsightly deflection of the whole nose, results in some cases during the transition from the nfantile to the adult facial conformation. Too extensive removal of the bony septum in the operation of submucous resection for the relief of this condition may cause sinking in of the bridge of the nose. More often, however, this is due to the destructive effect of congenital syphilis.

Accessory sinuses.—The communication of these air sinuses with the nasal fossæ are of great clinical importance. The **sphenoidal sinus** opens high up into the spheno-ethmoidal recess. **The posterior ethmoidal sinuses** open into the superior meatus under cover of the superior concha. The infundibulum of the **frontal sinus, the anterior** and **middle ethmoidal** and the **maxillary sinus** all communicate with the middle meatus under cover of the middle concha. The orifice of the **maxillary sinus** lies at the lowest part of the hiatus semilunaris into the front and upper end of which the frontal sinus opens. Consequently infected fluid may trickle down from the latter into the maxillary sinus. The orifice of this sinus is placed high up in its medial wall so that fluid does not drain away from it readily in case of infection. When the head is held forward in a stooping position some of the pus or mucus may escape from the nostrils, since in this position the fluid contents more readily reach the orifice.

The naso-lacrimal duct which carries the tears into the nose opens into the front and upper part of the inferior meatus under cover of the inferior concha.

THE NECK

The topics considered in the neck are the landmarks, thyreoid gland, sterno-mastoid, clavicle, triangles and cervical ribs.

Bony and cartilaginous landmarks.—The body of the hyoid is nearly on a level with the angles of the jaw, and the interval between the third and fourth cervical vertebræ (fig. 1097). With the head in the usual erect position it lies a little higher than the chin. It divides the front of the neck into supra- and infra-hyoid regions, convenient for remembering the distribution of the deep fascia. On either side of the body are the great cornua, with the lesser cornua attached to their upper borders at the junction with the body. The upper borders of these are the guides to the lingual arteries. The outline and mobility of the body and the great cornua are easily determined by relaxing the deep fascia and pushing the bone over to the opposite side. Below the hyoid is the thyreo-hyoid space, which corresponds with the epiglottis and the upper aperture of the larynx. Thus, if the throat be cut above the hyoid, the mouth will be opened and the tongue cut into; if the thyreo-hyoid space be cut, the pharynx would be opened and the epiglottis wounded near its base. In the former case the lingual and external maxillary are the most likely vessels to be wounded; in thyreo-hyoid, the commonest cut-throat, the superior thyroid vessels, and the superior laryngeal nerve. The projection of the thyreoid notch, about 2.5 cm. (1 in.) below the hyoid, is much more distinct in men than in women or children. It does not appear before puberty, and thus flatness of the thyreoid must be expected when the landmarks for tracheotomy are sought for in children with short fat necks.

The cricoid, on the other hand, is always to be made out. It corresponds in horizontal plane to the following:—(1) The sixth cervical vertebra. (2) The junction of pharynx and œsophagus: from the narrowing of the tube here, foreign bodies may lodge at this point and cause dyspnœa by pressing on the air-tube in front. The cricoid is taken as the centre of the incision in œsophagotomy, and also for ligature of the common carotid. (3) The junction of larynx and trachea. (4) The crossing of the omo-hyoid over the common carotid. (5) The middle cervical ganglion. Above the cricoid is the crico-thyreoid membrane. In laryngotomy, the deepest part of the incision should be kept to the middle line for fear of injuring the crico-thyreoids, and as near the cricoid as possible, so as to avoid the neighbourhood of the vocal cords and the small crico-thyreoid vessels. The space is always small, and, after middle life, increasingly rigid.

The distance between the cricoid and the manubrium is only about 3.7 cm. ($1\frac{1}{2}$ in.). When the neck is stretched, about 1.8 cm. ($\frac{3}{4}$ in.) more is gained. Thus, as a rule, there are not more than seven or eight tracheal rings above the sternum. Of these, the second, third, and fourth are covered by the thyreoid isthmus.

The parts met with in the middle line—(*a*) above, and (*b*) below, the isthmus—high and low tracheotomy—should be borne in mind: (*a*) Skin, superficial fascia, branches of transverse cervical and infra-mandibular nerves, lymphatics, cutaneous arteries, anterior jugular veins—with their transverse branches smaller above—deep fascia, sterno-hyoids, cellular tissue, superior thyreoid vessels, and pre-tracheal layer of deep fascia. The importance of this last is two-fold, as, first, the tube in tracheotomy may be passed between it and the trachea, and after a wound in this region this layer, continuous with the pericardium, may conduct discharges into the mediastina. (*b*) The surface structures are much the same, but the anterior jugular veins and their transverse branches are much larger. The inferior thyreoid veins are also larger. A thyreoidea ima may be present, and the innominate artery, especially in children, may be 1.2 cm. ($\frac{1}{2}$ in.) above the sternum. The trachea is also smaller, deeper, and less steadied by muscles. The thymus, too, in young children, may prove a difficulty. Thus, in children, the high operation, incising the cricoid and crico-tracheal membrane, if needful, is to be preferred. The cricoid is, however, not to be incised, if possible; the higher the tube is inserted, the greater the irritation.

The suprasternal notch, between the sternal heads of the sterno-mastoids in on a level with the disc between the second and third thoracic vertebræ. Just below the level of the cricoid cartilage, on deep pressure at the anterior border of the sterno-mastoid the transverse process of the sixth cervical vertebra may be felt. It is known as Chassaignac's carotid tubercle, and the common carotid may be compressed against it. Compression below it will command the vertebral artery as well.

The **thyreoid gland** enclosed in a capsule of deep fascia derived from the pre-tracheal layer (fig. 1070) is closely connected by this to the upper trachea and larynx. The upper somewhat pointed extremity of each lateral lobe reaches to the upper and back part of the thyreoid cartilage; here enter the superior thyreoid vessels. The lower layer and rounded extremity reaches to the fifth or sixth tracheal ring; its posterior and lower aspect is in relation to the inferior thyreoid vessels and the recurrent nerve; the lateral lobe, posteriorly, also overlaps the carotid sheath, which may be infiltrated in malignant disease of the thyreoid. The thyreoidea ima has been mentioned above.

The isthmus in the adult is opposite to the second, third, and fourth tracheal rings. At its upper border is an arterial arch formed by the superior thyreoids; over the anterior surface of the gland and isthmus the inferior thyreoid veins take origin in a plexus. The upper border of the thymus (fig. 1100) may be in relation with the lower border of the isthmus. From the upper border of the latter, the pyramidal lobe, especially on the left side, is often present, reaching by a pedicle to the hyoid. The pyramidal lobe, when present, is the persistent remnant of the thyreo-glossal duct, and occasionally cystic outgrowths persist obstinately as remnants of this duct, in the middle line, above, behind, and below (the commonest form) the hyoid bone.

In short-necked people the thyreoid is relatively lower in relation to the sternum, and enlargements of the gland are apt to become mainly intra-thoracic. An enlargement of the thyreoid is liable to give trouble by pressure on (1) the trachea, which is compressed laterally between the lateral lobes; (2) the œsophagus; (3) the internal jugular vein and carotid artery; (4) the recurrent laryngeal or cervical sympathetic nerves.

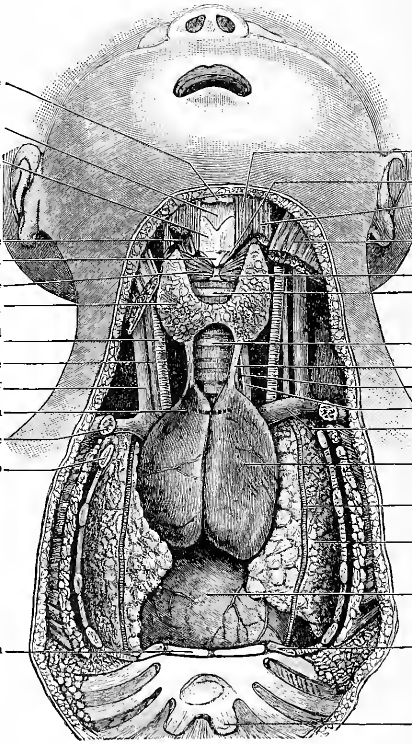
Parathyreoids.—These small glands, about the size of a pea, vary somewhat in number and situation. There are usually four—two behind each lateral lobe. The upper glands lie imbedded in the capsule of the thyreoid about the junction of the middle and upper thirds of the lateral lobes on the posterior aspect. The lower pair lie nearer the lower poles of the lateral lobes, sometimes separated from them by a distinct interval. Excision of all the parathyreoids gives rise to tetany in animals.

The **sterno-mastoid** is the landmark for several important operations. Its medial border, the thicker and better marked of the two, overlaps the carotids;

the common carotid corresponding, as far as the upper border of the thyreoid, with a line drawn from the sterno-clavicular joint to midway between the mastoid process and the angle of the jaw. The artery can be best compressed above the level of the cricoid, as here it is less deeply covered. The student should recall the deep relations of the sterno-mastoid, which he may classify as vessels, nerves, muscles, glands, and bones; or, according to their position, (1) those above the level of the angle of the jaw; (2) those between the angle of the jaw and the omo-hyoid; (3) those below the omo-hyoid.

Of the two heads of the sterno-mastoid, the sternal is the thicker and more prominent, the clavicular the wider. A stab through the interval which lies between the two heads might wound the bifurcation of the innominate on the right side, and the common carotid on the left, the internal jugular, vagus, and phrenic veins, according to the direction of the wound.

Fig. 1100.—Thymus Gland in a Child at Birth.



The **anterior jugular,** commencing in branches from the submaxillary and submental regions, descends at first in the superficial fascia between the middle line and anterior border of sterno-mastoid, perforates the deep fascia just above the clavicle, here entering Burns's space (p. 1361); it then curves laterally to pass beneath both origins of the sterno-mastoid a little above the clavicle, to end usually in the external jugular.

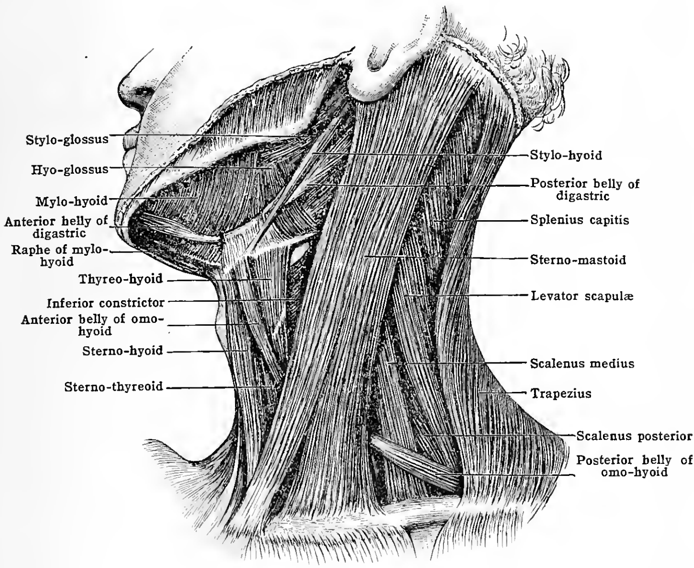
When distended, a large communicating branch between it and the common facial, which runs along the anterior border of the sterno-mastoid, must always be remembered in operations for removal of glands, etc. The varying level at which the external jugular crosses the lateral border of the clavicular origin must be remembered in such operations as tenotomy here. These veins vary in size inversely to each other; the anterior jugulars are joined by numerous transvesre branches and become larger below. They have no valves.

Of the chief arteries to the sterno-mastoid, that from the superior thyreoid will be divided in gature of the common carotid; that from the occipital runs with the spinal accessory nerve.

Behind the sterno-clavicular joint lies the commencement of the innominate veins, the bifurcation of the innominate artery on the right, and the common carotid artery on the left; deeper still lie the pleura and lung.

The clavicle.—This bone can be felt beneath the skin in its whole length. It forms the only bony connection between the upper limbs and the trunk. As one traces it laterally toward the acromial end, it rises somewhat, particularly in children and in subjects of good muscular development. The skin over it is thin but very mobile, and consequently is not often wounded. The most important posterior relations of this bone are, passing from the medial end laterally, the subclavian vein, the subclavian artery, and the cords of the brachial plexus as they lie on the first rib.

Fig. 1101.—Anterior and Lateral Cervical Muscles.



The vein occupies the angle between the first rib and the clavicle, and hence is, as a rule, the first structure compressed in growths of this bone. The artery lies on a deeper plane behind the mid-point of the clavicle, and the nerve cords extend a little further laterally. The subclavius muscle forms a protective cushion between the bone and these important structures, and this accounts for the rarity of injury to them in fracture of the clavicle. Behind the medial half of the clavicle the apex of the lung extends upward into the neck to a height of 2.5 – 3.7 cm. ($1–1\frac{1}{2}$ in.), and consequently is liable to be wounded by a stab in the root of the neck.

Cervical triangles.—In front of the sterno-mastoid is the **anterior triangle,** which is **subdivided into three smaller triangles** by the digastric muscle above, and the anterior belly of the omo-hyoid below (fig. 1101). These smaller triangles are called, from above, the submaxillary, the superior and inferior carotid triangles.

The **submaxillary or digastric triangle** is bounded above by the jaw, and a line drawn back to the mastoid process; below, by the digastric and stylo-hyoid muscles; and in front by the middle line of the neck.

This space contains the submaxillary gland, and embedded in the gland is the external maxillary artery, the facial vein lying superficial to the gland; deeper than the gland are the submental vessels and the mylo-hyoid vessels and nerve. Posteriorly, and separated from the above structures by the stylo-mandibular ligament, which subdivides the triangle into a submaxillary and parotid part, is the upper part of the external carotid artery running up into the parotid gland, where it gives off its two terminal and the posterior auricular branches. More deeply lie the internal jugular vein, internal carotid artery, and the vagus. The floor of the triangle is formed by the mylo-hyoid, hyo-glossus, and superior constrictor. The lingual artery may be tied here, or, better, in order to get behind the dorsalis linguæ, close to its origin, by an incision similar to that for exposing the external carotid.

The **hypoglossal** is a guide to the carotids and the occipital artery at the lower border of the digastric, and farther forward, to the subjacent lingual, from which it is separated by the hyo-glossus.

The **superior carotid triangle** is bounded above by the digastric, below by the omo-hyoid, and behind by the sterno-mastoid. It contains the upper part of the common carotid and its branches, the external being at first somewhat anterior to the internal. All the branches of the external carotid, save the three just given, are found in this space, together with their veins, the internal jugular vein, the vagus and sympathetic nerves, and, for a short distance, the accessory, together with those nerves which lie in front of and behind the carotids.

Ligature of the common carotid is usually performed at the 'seat of election,' where the vessel is more superficial, *above the omo-hyoid*. An incision with its centre opposite the cricoid is made 7.5 cm. (3 in.) long in the line of the carotid artery. The deep fascia along the anterior border of the sterno-mastoid having been divided, the cellular tissue beneath is opened up, the omo-hyoid identified and drawn down or divided. The sterno-mastoid is next drawn well laterally, and the artery felt for. At this stage, such veins as the communication between the common facial and the anterior jugular and the superior and middle thyreoids may give trouble. The sheath is next opened well to the medial side, opposite to the cricoid cartilage, the ascending cervical, when seen, being avoided. If the internal jugular be distended, it may be drawn aside with a blunt hook, or pressure made lightly in the upper angle of the wound. The needle should be passed from the lateral side in very close proximity to the lateral and back part of the artery, so as to avoid the vein and vagus. Ligature *below the omo-hyoid* is rendered more difficult by the presence of the anterior jugular, the pretracheal muscles, an overlapping thyreoid gland, especially if enlarged, the greater depth of the artery, especially on the left side and, here also, the closeness of the internal jugular. The *collateral circulation* is given at p. 1360. Ligature of the external carotid, otherwise difficult, is rendered very simple by first exposing the bifurcation of the common carotid artery, the incision similar to the last being prolonged upward. Here the facial and lingual veins and hypoglossal nerve cross the trunk, over which also lie some of the deep cervical glands. The ligature is usually placed between the superior thyreoid and lingual branches.

Allusion must here be made to **the chief structures liable to be met with in operations on the neck.** These are the **internal jugular**, the **accessory**, and **phrenic** nerves, the **vagus** and **hypoglossal**, the **thoracic duct**, low down and deep on the left side, the **œsophagus** and **recurrent nerve** in difficult operations on the thyreoid gland. Of these, the **internal jugular** is, in some ways, the most important. Glands, tuberculous or epitheliomatous, are often adherent to its sheath, especially those which drain the submaxillary group. When this condition is present or suspected, it is always well to begin the dissection low down in the inferior carotid triangle, where the structures are probably normal and the landmarks easy to identify. In infective thrombosis of the transverse sinus the internal jugular is often tied opposite to the cricoid cartilage, being either divided between two ligatures, or, if the thrombus has extended downward, as much of the vein as is possible is removed. This vein contains only a single pair of valves low down in the neck. In all operations here on it and the other two jugulars, the risk of entry of air is to be remembered. The **accessory** and **phrenic nerves** are alluded to on p. 1360.

The **inferior carotid** or **tracheal triangle** is bounded above by the omo-hyoid, behind by the sterno-mastoid, and in front by the middle line of the neck. It contains the lower part of the carotid sheath and its contents, with, behind it, the inferior laryngeal nerve and inferior thyreoid vessels, and to the medial side the trachea, thyreoid gland, and œsophagus. More deeply are the vertebral vessels; on the left side is the thoracic duct.

The position of the **branches of the external carotid** should be remembered. The great cornu of the hyoid and the ala of the thyreoid are landmarks for the origin of most of them.

The **superior thyreoid,** arising just below the level of the great cornu of the hyoid bone, passes downward and forward to the back part of the thyreoid cartilage and upper part of the thyreoid body. Many of its branches are important in surgery. The **superior laryngeal** perforates the thyreo-hyoid membrane. The **sterno-mastoid** passes laterally into the middle of the muscle, across the carotid sheath. The **crico-thyreoid** crosses the space of the same name just below the lower border of the thyreoid cartilage. The small **hyoid** branch runs to the lower border of the hyoid bone. Anastomosing branches of the superior thyreoid form an arch along the upper border of the isthmus. The **lingual artery** arises from the parent trunk, opposite the tip of the great cornu of the hyoid, and passes forward just above the great cornu, crossed by the hypoglossal, and thence to the side of the tongue. In the first part of its course, before it reaches the hyo-glossus, it is curved, at first ascending, and then, having descended slightly, before it reaches the hyo-glossus, and while it lies under it, its curve is gentle, with the concavity upward; beyond the hyo-glossus, as it lies on the muscles of the tongue beneath the mucous membrane, it is tortuous. The **lingual vein,** it will be remembered, does not run with its artery, but lies superficial to the hyo-glossus. It receives the two small venæ comitantes which run with the lingual itself just before it crosses the common carotid. The line of the **external maxillary** (facial) **artery** (fig. 1093), which often arises with the lingual, has been given on p. 1343. The **occipital artery,** starting on the same level as the facial (i. e., at a point a little above and outside the tip of the great cornu of the hyoid bone), follows a line drawn upward and laterally, first to the interval between the transverse process of the atlas and the mastoid process, the former bone being felt just below and in front of the tip of the latter; thence, lying in the occipital groove of the mastoid, the artery ascends gradually, enters the scalp, together with the great occipital nerve, a little medial to a point midway between the external occipital protuberance and the mastoid process, to follow, tortuously and superficial to the aponeurosis, the line of the lambdoid suture.

The surface marking of the **digastric** and **omo-hyoid,** which subdivide the anterior triangle into the three smaller subtriangles above described, should be noted. The line of the **posterior belly of the digastric** corresponds to one drawn from the apex of the mastoid process to a point just above the junction of the great cornu and body of the hyoid bone; and from this spot, which gives the point of meeting of the two tendons, one slightly curving upward to a point just behind the symphysis menti, would give that of the **anterior belly.**

To trace the **omo-hyoid,** a line should be drawn from the lower margin of the side of the hyoid bone obliquely downward, so as to cross the common carotid opposite the cricoid cartilage and thence curving laterally under the sterno-mastoid at the junction of its middle and lower thirds, and then onward and still laterally parallel with and a little above the clavicle, as far as its centre.

Posterior triangle.—This shows in its lower part a wide depression, the supraclavicular fossa. Here the brachial plexus may be felt, and, by pressure downward and backward immediately behind the clavicle, just lateral to and behind the lateral margin of the sterno-mastoid, the pulsation of the subclavian artery can be stopped against the first rib.

The supra-clavicular fossa should be opened out by depressing the arm, and parts relaxed by carrying the shoulder forward and turning the head to the same side. This vessel curves upward and laterally from behind the sterno-clavicular joint to disappear behind the centre of the clavicle, the highest point of the curve being 1.2 to 2.5 cm. ($\frac{1}{2}$ to 1 in.) above the bone. The artery on the left side lies more deeply than the right, and does not rise so high into the neck. The subclavian vein lies at a lower level, separated by the scalenus anterior, and under cover of the clavicle. Into the above curve rise the pleura and lung. The pleura must be expected to rise 2.5 cm. (1 in.) above the clavicle, behind the clavicular head of the sterno-mastoid.

The **transverse scapular** and **transverse cervical vessels** run laterally, parallel with the clavicle. The former lies behind the bone and subclavius; the latter also runs laterally in a transverse direction, across the root of the neck, but on a slightly higher plane, and thus a little above the clavicle.

Ligature of the third part of the subclavian is best performed by an angular incision, the horizontal portion along the centre of the clavicle, and the vertical one along the posterior border of the sterno-mastoid, with partial division of this and the trapezius when closely adjacent. The chief points to bear in mind are the venous plexus into which the external jugular, transverse cervical, transverse scapular, and cephalic veins enter; the omo-hyoid and division of the fascia which ties this to the clavicle; identification of the lateral margin of the scalenus anterior and the scalene tubercle; care of the transverse scapular artery and the descending branch of the transverse cervical. The needle is passed from above downward so as not to include the lowest cord of the brachial plexus, the vein, if distended, being depressed with a blunt hook. If the nerve to the subclavius be seen, it must be uninjured, as it occasionally forms an important part of the phrenic. The *collateral circulation* is given at p. 1360.

Crossing the sterno-mastoid, a little obliquely, in a line drawn from a point just below and behind the angle of the jaw which marks its origin in the union of the posterior part of the internal maxillary and the posterior auricular veins to the centre of the clavicle, runs the **external jugular vein.** Above, it lies between the platysma and deep fascia, and is accompanied by the group of superficial cervical nodes (p. 709). About 3.7 cm. ($1\frac{1}{2}$ in.) above the clavicle it perforates the deep cervical fascia, its coats being blended with the opening. Gentle pressure with a finger at this point renders the vein above clearly visible. The dilated part between this point and the subclavian vein is called the sinus, and is marked by two valves, neither of which is usually perfect.

Opening into the external jugular, in the middle or lower third of its course, is the **posterior external jugular,** a vessel which begins in the occipital region superficially and runs down in front of the anterior border of the trapezius, across the posterior triangle.

The **accessory** nerve, having crossed the transverse process of the atlas at a point lying a little below and in front of the apex of the mastoid, enters the anterior border of the sterno-mastoid at about the junction of the upper and middle thirds of the muscle. Having traversed the muscle obliquely, it leaves it usually at a point a little lower down, pursues a similar course across the posterior triangle and disappears under the anterior border of the trapezius, to enter into the subtrapezial plexus with the third and fourth cervical nerves.

Above it is accompanied by a branch from the occipital, below by the transverse cervical artery. It is always seen in thorough operations on the upper deep cervical glands. The nerve is resected in spasmodic torticollis, and in recent years inveterate facial paralysis has been treated by anastomosing the facial to this nerve or the hypoglossal. A line drawn from midway between the tip of the mastoid and the angle of the mandible along the above given course of the nerve would denote its position.

Just above the centre of the sterno-mastoid, the **small occipital, great auricular,** and **cutaneous cervical nerves** emerge, the first passing upward and backward to the scalp, the second upward and forward across the upper part of the sterno-mastoid to the ear, and the last turning straight forward to the front of the neck. The small occipital and great auricular are often in intimate association with the accessory at its exit from the muscle. At this point also care must be taken not to injure the nerve in removal of glands from the posterior triangle.

The **phrenic nerve,** taking its largest root from the fourth cervical, would begin deeply about the level of the hyoid bone; thence descending under the sterno-mastoid, and, passing obliquely medially across the scalenus anterior (the posterior borders of the above two muscles roughly correspond to each other in the lower part of the neck), it descends under the subclavian vein and clavicle to enter the thorax.

When the internal jugular is distended, its lateral border will be liable to overlap this nerve. The relations of the *scalenus anterior* should be noted here. In addition to the phrenic, which runs with a slight obliquity medially and is in close contact with the muscle, the following structures cross it medio-laterally: the subclavian vein and termination of the external jugular, the transverse scapular and transverse cervical vessels, and the omo-hyoid. At its medial margin are the thyreo-cervical trunk and vertebral arteries, and over them, the internal jugular. Behind it are the subclavian artery, the brachial plexus, and pleura.

The level of the **brachial plexus** (upper border) would be given by a line drawn from the cricoid cartilage to the centre of the clavicle. The lowest, medial cord (eighth cervical and first thoracic, giving off chiefly the ulnar, medial head of median, and medial antibrachial cutaneous) is just above and behind the subclavian artery. Its importance in ligature of the artery has been referred to (p. 1359).

In paralysis of the newly born, after some violent manipulation, it is usually the upper and lateral cord (fifth nerve, and axillary and median chiefly) which suffers, elevation and abduction at the shoulder and flexion at the elbow-joint being lost.

Collateral circulation after ligature of the common carotid (fig. 1102).—This takes place by means of (1) the free communication which exists between the opposite carotids, both without and within the cranium; and (2) by enlargement of the branches of the subclavian artery on the same side as that on which the carotid has been tied. Thus, outside the cranium, the superior and inferior thyreoids are the chief vessels employed (fig. 1102). Within the cranium the vertebral replaces the internal carotid.

Collateral circulation after ligature of the second and third parts of the subclavian (fig. 1102).—Here the following three sets of vessels are those chiefly employed:—

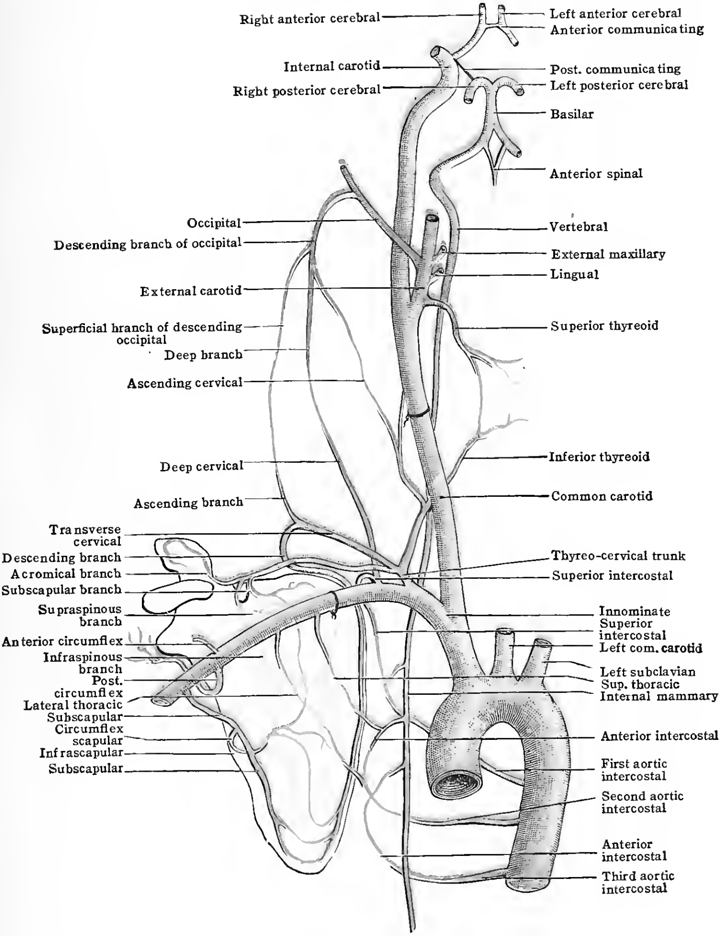
The transverse scapular, the transverse cervical,	with	The thoraco-acromial, infra- and subscapular, and circumflex scapular.
The superior intercostal, the aortic intercostals, and the internal mammary,	with	The lateral thoracic and subscapular arteries.
Numerous unnamed branches passing through the axilla from branches of the subclavian,	with	Branches of the axillary.

Deep cervical fascia.—The arrangement of this must be remembered—(*a*) above, and (*b*) below, the hyoid bone. The latter is far more important.

(*a*) **Arrangement above the hyoid bone.**—Here two chief processes can be made out:—(i) one, continuous with that in front of the sterno-mastoid, traced upward from the hyoid bone, encloses the submaxillary gland, passing over the mylo-hyoid, and, ascending, is connected with the lower border of the mandible, gives off the masseteric and parotid fasciæ, and is attached to the lower border of the zygoma, and, more posteriorly, to the mastoid and linea nuchæ suprema. (ii) A special process, which forms the stylo-mandibular ligament, is important in its power of checking over-action of the external pterygoid. By both these processes the anterior border of the sterno-mastoid is tied firmly forward to the mandible about its angle, and more deeply to the styloid process. This renders all operations under the upper part of the muscle, e. g., the removal of glands, extremely difficult.

(*b*) **Below the hyoid bone.**—The importance of the fascia here is infinitely greater. **Four layers** must be remembered; (i) **Superficial;** (ii) **pretracheal;** (iii) **prevertebral;** (iv) **carotid.** (i) **Superficial.** This starts from the ligamentum nuchæ, encases the trapezius, forms the roof of the posterior triangle where it is perforated by branches of the superficial cervical nerves and the external jugular

FIG. 1102.—THE COLLATERAL CIRCULATION AFTER LIGATURE OF THE COMMON CAROTID AND SUBCLAVIAN ARTERIES.
(A ligature is placed on the common carotid and on the third portion of the subclavian artery.)



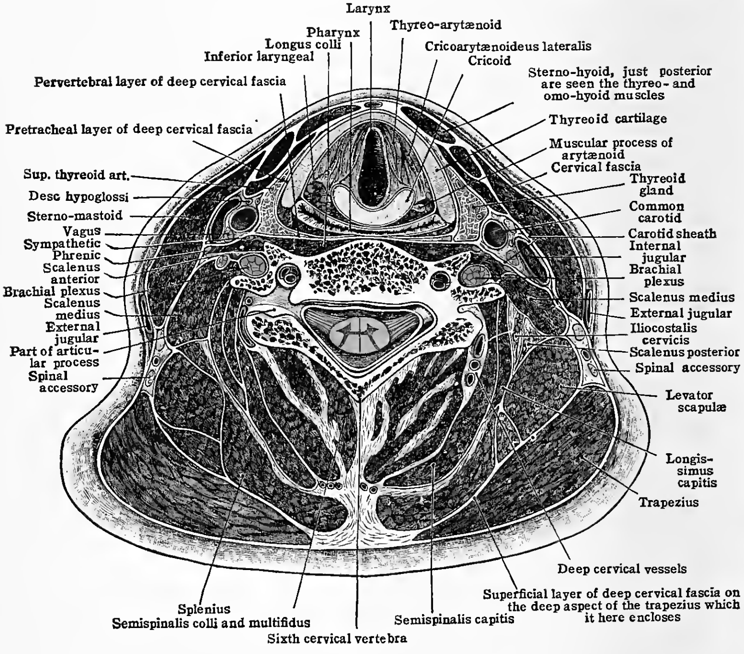
vein. Passing on it encloses the sterno-mastoid; and, passing over the anterior triangle, it meets its fellow in the middle line.

Thin behind, it is thickened anteriorly. Behind this thickened union lie the anterior jugular veins. Below, at a varying distance below the thyreoid cartilage, this layer divides into two, attached to the front and back of the manubrium. Between these (**Burns's space**) lie some fat, a small gland, a communicating branch between the anterior jugulars and a small portion of the veins, and the sternal heads of the sterno-mastoids. The sheath to the depressors of the hyoid bone is partly derived from this layer, partly from the next. Laterally, this layer gives a sheath to the posterior belly of the omo-hyoid, is attached to the clavicle, and passing on, is continuous with the sheath to the subclavius and coraco-clavicular fascia.

(ii) **Pretracheal** or **middle.** This lies under the depressors of the hyoid, over the trachea, also encasing the thyreoid gland. Farther laterally it helps, together with the prevertebral, to form the carotid sheath. Traced downward, the pretracheal layer passes over the trachea into the thorax (middle mediastinum)

As it descends, it encases the left innominate vein, and ends by blending with the fibrous layer of the pericardium. Hilton suggested that the attachment of this fascia above, and that of the central tendon of the diaphragm below, to the pericardium served to keep this sac duly stretched, and so prevented any pressure of the lungs upon the heart.

FIG. 1103.—SECTION OF NECK THROUGH THE SIXTH CERVICAL VERTEBRA. (Braune.)



(iii) **Prevertebral.** This layer passes over the longus colli and capitis upward to the base of the skull, and downward over the longus colli behind the œsophagus into the posterior mediastinum. Laterally it helps to form the carotid sheath, and, lower down, gives a sheath to the subclavian artery and so to the axillary. (iv) **The carotid sheath.** This is formed by septa from i, ii, and iii, meeting under the sterno-mastoid (fig. 1103).

The following uses and important points with regard to the anatomy of the deep cervical fascia should be noted:—(A) It **forms certain definitely enclosed spaces** in which pus or growths may form, and by the walls of which these morbid structures may be tied down and thus rendered difficult of diagnosis, while their increasing pressure may embarrass the air-passages, etc. Thus: (1) In the first space, which lies between No. 1 and the skin, the structures met with, the platysma and superficial branches of the cervical plexus, are unimportant. Any abscess here is prone to extend, but superficially. (2) In the second space, between the superficial and middle layers, lies a narrow space containing loose cellular tissue and lymphatic glands. Suppuration here is very common, but usually comes forward. (3) This is the largest and most important of all. From its contents it has been called the visceral **compartment.** (Stiles.)

It is bounded in front by the middle, and behind by the prevertebral layer. Its contents are—larynx, trachea, œsophagus, thyreoid, carotid sheath, glands; and below, brachial plexus, subclavian artery, and abundant loose cellular tissue for the movements of the neck. Suppuration is somewhat rarer here; but either pus or growths, if confined in this space, may have baneful effects, from pressure, or from their tendency to travel behind the sternum. (4) This space between the prevertebral layer in front and muscles behind, is very limited. Retropharyngeal abscess forms here, and the dyspnœa it causes is thus explained. The origin of such abscesses is chiefly twofold, either in one of the highest deep cervical nodes, e. g., from infection of the naso-pharynx (p. 717), or from disease of the upper cervical vertebræ. In the former cases (Stiles, Chiene) the suppuration will be *in front* of the prevertebral fascia, pointing toward the pharynx; in the latter *behind* the above fascia, spreading laterally, behind the carotid sheath. In making his incision, now along the posterior border of the sterno-mastoid, the surgeon should keep close to the transverse processes of the vertebræ, to avoid opening the visceral compartment and infecting the structures in it. (B) The deep cervical fascia gives **sheaths** or **canals** to certain veins which perforate it, e. g., the external jugular. These are thus kept patent, and a ready passage of blood ensured from the head and neck. Further, this fact accounts for the readiness with which air may enter veins, in operations low down in the neck. The carotid sheath is another and different instance. (C) It **helps to resist atmospheric pressure.** (D) Hilton's suggestion as to its **action on the pericardium** has already been mentioned.

The lymphatic nodes of the head and neck have already been described. (See Section VI, Lymphatic System.)

THE THORAX

The bony landmarks of the thorax will be discussed first, followed by the structures of the thoracic wall, the lungs and pleura, and finally the heart and pericardium.

Bony landmarks.—The top of the sternum corresponds (in inspiration) to the fibro-cartilage between the second and third thoracic vertebræ, and is distant about 6.2 cm. ($2\frac{1}{2}$ in.) from the spine. In the newborn child it corresponds to the middle of the first thoracic vertebra (Symington). If traced downward, the subcutaneous sternum presents a ridge (sternal angle of Louis) opposite to the junction of the manubrium and body, and the second costal cartilages on either side; this ridge usually corresponds to the disc between the fourth and fifth thoracic vertebræ. At the lower extremity of the sternum the xiphoid cartilage usually retires from the surface, presenting the depression of the epigastric angle or 'pit of the stomach.' This is opposite to the seventh costal cartilages and the expanded upper end of the recti, and corresponds to the tenth thoracic vertebra behind.

Parts behind manubrium.—There is little or no lung behind the first bone of the sternum, the space being occupied by the trachea and large vessels, as follows;

The left innominate vein crosses behind the sternum just below its upper border. Next come the great primary branches of the aortic arch. Deeper still is the trachea, dividing into its two bronchi opposite to the junction of the first and second bones of the sternum. Deepest of all is the œsophagus. About 2.5 cm. (1 in.) below the upper border of the sternum is the highest part of the aortic arch, lying on the bifurcation of the trachea. (Holden.) (Fig. 1104).

Sterno-clavicular joint.—The expanded end of the clavicle and the lack of proportion between this and the sternal facet, on which largely depends the mobility of this, the only joint that ties the upper extremity closely to the trunk, can be easily made out through the skin. Its strength, considerable when the rarity of dislocation compared with fracture of the clavicle is considered, depends mainly on its ligaments, the buffer-bond meniscus, the costo-clavicular ligament, which checks excessive upward and backward movements, and the fact that the elastic support of the first rib comes into play in strong depression of the shoulder as in carrying a weight. The relative weakness of the anterior ligament determines the greater frequency of anterior dislocation of the clavicle at this joint.

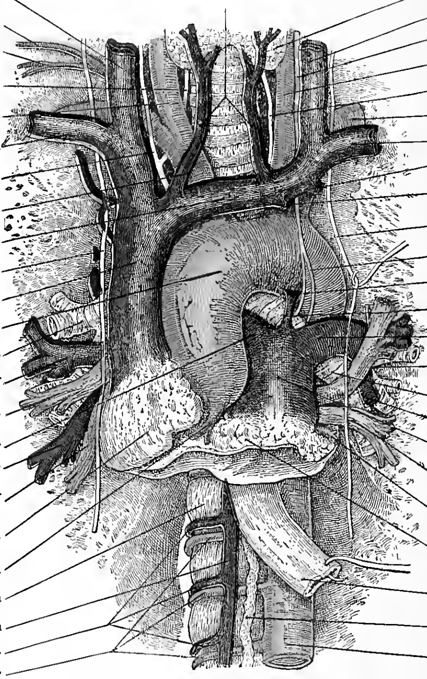
Behind the joint lie, on the right side, the innominate artery, right innominate vein, and pleura; on the left, the left innominate vein, the left carotid, and the pleura.

Acromio-clavicular joint.—On tracing the clavicle laterally, it is found to rise somewhat to its articulation with the acromion. This joint has very little mobility, and owes its protection to the strong conoid and trapezoid ligaments hard by. Owing to the way in which the joint-surfaces are bevelled, that of the clavicle looking obliquely downward, and resting upon the acromion, it is an upward displacement of the clavicle which usually takes place.

Ribs.—In counting these, the position of the second is denoted by the transverse line at the junction of the manubrium and body of the sternum. It is well always to count ribs from this point and never from below, as the twelfth rib varies in size and may be obscured by the sacro-spinalis muscles. The *nipple* in the male, lies between the fourth and fifth, nearly an inch lateral to their cartilages. The lower border of the great pectoral corresponds to the fifth rib. The seventh, the longest of the ribs, is the last to articulate by its cartilage with the sternum. When the arm is raised, the first three digitations seen of the serratus anterior correspond to the fifth, sixth, and seventh ribs. The ninth rib

FIG. 1104.—THE ARCH OF THE AORTA, WITH THE PULMONARY ARTERY AND CHIEF BRANCHES OF THE AORTA.

(Modified from a dissection in St. Bartholomew's Hospital Museum.)



is the most oblique. The eleventh and twelfth can be felt lateral to the sacro-spinalis. Owing to the obliquity of the ribs, their sternal ends are on a much lower level than their vertebral extremities.

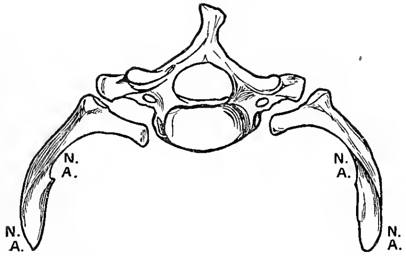
'Thus the first rib in front corresponds to the fourth rib behind, the second to the sixth, the third to the seventh, the fourth to the eighth, the fifth to the ninth, the sixth to the tenth, and the seventh to the eleventh. If a horizontal line be drawn round the body from before backward at the level of the inferior angle of the scapula, while the arms are at the sides, the line would cut the sternum in front between the fourth and fifth ribs, the fifth rib at the nipple line, and the ninth rib at the vertebral column.' (Treves.) The most frequently broken are the sixth, seventh, and eighth. The upper four and the two lowest ribs are best covered by soft parts, and, in the case of the former, the shoulder and arm take off some of the violence that would otherwise reach them. The way in which the ribs are embedded in the soft parts (fig. 1106), and the fact that the fragments are often held in place by the periosteum, account for the difficulty which is often met with in detecting crepitus. The intercostal spaces are wider in front than behind. The three upper are the widest of all.

Cervical ribs.—It occasionally happens that the rib element of the seventh cervical vertebra, normally fused with the true transverse process, is segmented off as a separate, though usually rudimentary, rib. This anomaly is generally bilateral. It occurred in 3 of 260 subjects (1.16 per cent.) examined by Wingate Todd.*

The anterior extremity of a cervical rib may, according to the degree of its development (1) lie free amongst the scalene muscles; (2) be connected with the sternum by a ligamentous prolongation; (3) articulate with the upper surface of the first thoracic at about its centre by a synchondrosis, or (4) form a complete rib, articulating by a costal cartilage with the sternum.

The lowest trunk of the brachial plexus formed by the eighth cervical and first thoracic roots, the subclavian artery and less commonly the subclavian vein, curve over the upper surface of these ribs. The abnormality owes its clinical importance to the pressure effects produced on the nerve trunk in a small proportion of the cases. This pressure is manifested by (1) pain, going on to anæsthesia down the medial side of arm, forearm and hand; (2) paralysis of the intrinsic muscles of the hand, producing the *main en griffe*, and to a less extent of the muscles of the forearm; (3) vascular effects (anæmia, gangrene, etc.), manifested chiefly in the hand. Todd has shown that these vascular effects are not due to mechanical pressure on the subclavian artery by the cervical rib as was formerly supposed, but are trophic lesions of the sympathetic (vasomotor) nerves. The vasomotor nerves to the arm mainly come from the second thoracic root by the communication it gives to the lowest cord of the brachial plexus, and so are exposed to pressure from the rib.

FIG. 1105.—CERVICAL RIBS, VIEWED FROM ABOVE. (× ½.) NN, IMPRESSION FOR LOWEST TRUNK OF BRACHIAL PLEXUS. AA, IMPRESSION FOR SUBCLAVIAN ARTERY. (T. WINGATE TODD.)



The same investigator has shown that similar symptoms may be produced occasionally by a first thoracic rib in cases where the brachial plexus has migrated caudad. In the living patient, unless a radiogram be taken showing all the vertebræ up to the base of the skull, it is not possible with precision to ascertain with which vertebra the highest rib present articulates.

Structures found in an intercostal space.—(1) Skin; (2) superficial fascia, with cutaneous vessels and nerves; (3) deep fascia; (4) external intercostal; (5) cellular interval between intercostals, containing trunks of intercostal vessels and nerves; (6) internal intercostals; (7) thin layer of fascia; (8) subpleural connective tissue; (9) pleura (fig. 1106).

The intercostal arteries are nine aortic and two from the superior intercostal. An aortic intercostal having given off its dorsal branch, lying beneath the pleura, crosses the space obliquely upward to gain the lower border of the rib above, enters the costal groove at the angle, and runs forward between the intercostal muscles to anastomose with the anterior intercostals from the internal mammary or musculo-phrenic. Hence the rule of making the incision in empyema above the upper margin of the lower rib and in front of the angle. Along the dorsal branch a vertebral abscess may track backward.

Internal mammary artery.—This descends behind the clavicle, the costal cartilages, and the first six spaces, about 1.2 cm. (½ in.) from the edge of the sternum. In the sixth intercostal space it divides into musculo-phrenic and superior epigastric acteries. Its venæ comitantes uniting join the innominate vein of the same side. A punctured wound of the artery is most easily secured in the second and third spaces; below, resection of part of a costal cartilage will be needed.

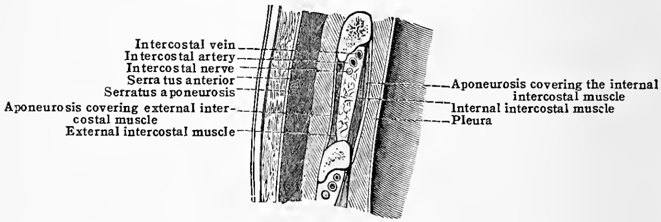
Structures passing through the upper aperture of the thorax.—If a section is made passing through the manubrium sterni, upper border of the first rib, and

* Journal of Anatomy and Physiology, Vol. 47, 1913.

upper part of the first thoracic vertebra, the following structures are met with:—(1) **In the middle line.** Sterno-hyoid and sterno-thyreoid muscles, with their sheaths of deep cervical fascia, cellular tissue in which are the remains of the thymus gland, the inferior thyreoid veins, the trachea and tracheal fascia, the œsophagus, and longus colli muscles. Between the trachea and œsophagus are the recurrent nerves. (2) **On each side.** The apex of the lung, covered by pleura, deep cervical fascia, and membranous cervical diaphragms ("Sibson's fascia") derived from the scalenes, rises about 3.7 cm. ($1\frac{1}{2}$ in.) above the first rib. Between it and the trachea and œsophagus lie the following: the internal mammary artery, the phrenic nerve; on the right side, the innominate vein and artery, with the vagus between the two, the cardiac nerves, and the right lymphatic duct. On the left side are the common carotid and subclavian arteries, with the left vagus between them, the cardiac nerves and the thoracic duct. Farthest back and on each side are the trunk of the sympathetic, the superior intercostal artery, and the first thoracic nerve.

The mamma.—This lies chiefly on the pectoralis major and slightly on the rectus abdominis and serratus anterior. It is usually described as reaching from the second to the sixth rib, and from the sternum to the anterior border of the axilla. It is most important to remember that the breast is often a much more extensive structure than would be included in the above very limited description. Thus—(1) the gland is not encapsuled at its periphery, its tissue branching and breaking up here to become continuous with the superficial fascia. (Stiles.) (2)

Fig. 1106.—Section of the Sixth Left Intercostal Space, at the Junction of the Anterior and Posterior Thirds. (Tillaux.)



The retinacula cutis contain lymphatics and, sometimes, mammary tissue. (3) There is a lymphatic plexus, and, often, minute lobules of gland tissue, in the pectoral fascia. (Heidenhain.) Fully one-third of the whole mamma lies posterior and lateral to the axillary border of the pectoralis major so that it reaches almost to the mid-axillary line. That part of the upper and lateral quadrant known as the axillary lobe is of especial importance from its reaching into close vicinity with the anterior pectoral group of axillary nodes (p. 719). In the male the nipple is usually placed in the fourth space, nearly 2.5 cm. (1 in.) lateral to the cartilages of the fourth and fifth ribs. On the nipple itself open the fifteen or twenty ducts which dilate beneath it, and then diverge and break up for the supply of the lobules. The skin over the areola is very adherent, pigmented, and fatless. Here also are groups of little swellings corresponding to large sebaceous follicles and areolar glands. The skin over the breast is freely movable, and united to the fascia which encases the organ, and thus to the interlobular connective tissue, by bands of the same structure—the retinacula cutis. Under the breast, and giving it its mobility, is a cellulo-fatty layer, the seat of submammary abscess.

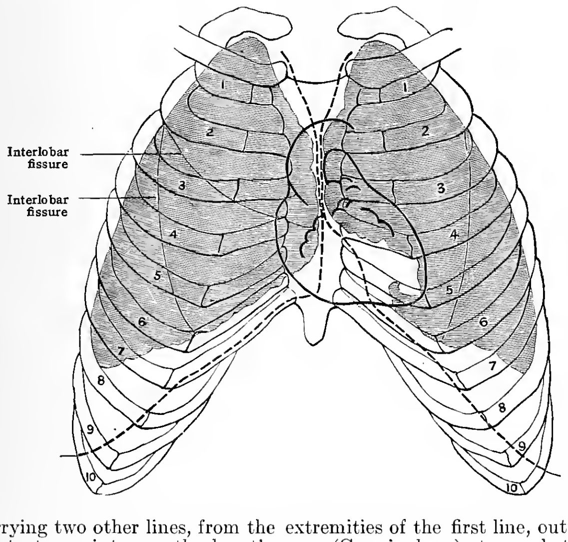
[1]The nerves which supply the breast are the anterior cutaneous branches of the second, third, fourth, and fifth intercostal nerves, and the lateral branches of the last three. The connection of these trunks serves to explain the diffusion of the pain often observed in painful affections of the breast. Thus pain may be referred to the side of the chest and back (along the above intercostal trunks), over the scapula, along the medial side of the arm (along the intercosto-brachial nerve), or up into the neck. The gland is supplied by the following arteries: the aortic intercostals of the second, third, fourth, and fifth spaces, similar intercostal branches from the internal mammary, which runs outward, two small branches to each space, perforating branches from the same vessel, one or two given off opposite to each space, the long thoracic and external mammary (when present) from the axillary.

The lymphatics have already been described (p. 721, fig. 566).

In removal of the breast elliptical incisions will usually suffice if employed on wide lines, and if attention be paid to the following points:—(1) Those details in the surgical anatomy already referred to, especially those bearing on the extensiveness of this organ, and the proportionate difference between seen and unseen disease. (2) The importance of removing in one continuous piece the whole breast, all the skin over it, the costo-sternal part of the pectoralis major, the pectoralis minor, the axillary fat, and lymphatics.

Outline of the lungs. Their relation to the chest-wall.—To map out the lung, a line should be drawn from the apex, a point about 2.5 cm. (1 in.) above the clavicle, a little lateral to the sterno-mastoid muscle, at the junction of medial and middle thirds of clavicle, obliquely downward, behind the sterno-clavicular joint, to near the centre of the junction of the first and second bones of the sternum. Thence, on each side, a line should be drawn slightly convex as far as a similar point on the sternum lying opposite the articulation of the fourth chondro-sternal joint. On the right side the line may be dropped as low as the sixth chondro-sternal joint; on the left the incisura cardiaca may be shown by drawing a vertical line along the middle line of the sternum, from the level of the medial extremities of the fourth costal cartilages to the lower end of the gladiolus, and

FIG. 1107.—OUTLINE OF THE HEART, ITS VALVES, THE LUNGS (SHADED), AND THE PLEURA. (Holden.) (Cf. fig. 437.)



by carrying two other lines, from the extremities of the first line, outward so as to meet at a point over the heart's apex (Cunningham); to mark this gap, a line should be drawn sloping laterally and downward from the fourth chondro-sternal articulation across the fourth and fifth interspaces, to a point about 3.7 cm. ($1\frac{1}{2}$ in.) below the left nipple (male) and 2.5 cm. (1 in.) to its medial side. This point, lying in the fifth space, marks the apex of the heart. Thence the line curves medially to the sixth costal cartilage, a little medial to its chondro-sternal junction, and in the lateral vertical line. Thus the lower part of the anterior surface of the right ventricle is not covered by lung. The lower border of the lung will be marked on the right side by a line drawn from the sixth chondro-sternal articulation across the side of the chest down to the tenth thoracic spine. The lower border of the left lung will follow a similar line, starting on a level with a similar joint (sixth chondro-sternal joint), but much farther laterally than on the right side, i. e., in the fifth space, about 7.5 cm. (3 in.) to the left of the middle line, or a point corresponding to the heart's apex. In the nipple-line the lung crosses the sixth rib, in the mid-axillary line the eighth, and opposite the angle of the scapula (the arms being close to the sides), the tenth rib. The position of the great fissure in each lung may be ascertained approximately by drawing a line curving downward and forward from the second thoracic spine to the lower border of the lung at the sixth costal cartilage; and the smaller fissure of the right lung extends from the middle of the foregoing to the junction of the fourth costal cartilage with the sternum. It will be seen from the above that there is little lung behind the manubrium. The connective tissue here between the lung margins contains the thymus, large up to the age of puberty, and, later, its remains. The hilus (root) of the lung is referred to on p. 1230.

The **pleura,** following much the same line as the lung above and in front, reaches lower down laterally and behind. Thus the two sacs starting from about 2.5 cm. (1 in.) above the medial third of the clavicle converge toward the angle of Louis (p. 1238); meeting here, they descend vertically, the left overlapping the right slightly, to the fourth chondro-sternal joint. Hence the *right* sac descends behind the sternum to the sterno-xiphoid junction and sixth chondro-sternal joint. Thence, as it curves to the back of the chest, it crosses the eighth rib close to the lateral vertical line (*vide supra*), the tenth in the mid-axillary, the eleventh in the line of the angle of the scapula, and thence toward the twelfth thoracic vertebra. On the *left* side the pleura parts company from the right at the level of the fourth chondro-sternal junction, deviating laterally and downward across the fourth and fifth interspaces; it then turns again slightly medially to meet the sixth costal cartilage. Thus, as in the case of the lung, but to a less extent, there is a small area of the pericardium, and, under it, the right ventricle uncovered by the pleura. Over the side and back of the chest, along its diaphragmatic reflection, the left pleura reaches a little lower than the right.

The *deepest part of the pleural sac* is where the reflection crosses the tenth rib or tenth space in the mid-axillary line. From this it ascends slightly as it curves back to the spine. (Cunningham.) *The relations of the pleura to the last rib* are of much importance to the surgeon in operations on the kidney. In the case of a twelth rib of ordinary length, the pleural reflection crosses it at the lateral border of the sacro-spinalis; when a rudimentary last rib does not reach the lateral border of this muscle, an incision carried upward into the angle between the eleventh rib and the sacro-spinalis will open the pleural sac. (Melsome.)

For **tapping the pleura** there are two chief sites:—(1) The sixth or seventh space in front of the posterior fold of the axilla. (2) The eighth space behind, in the line of the angle of the scapula. For **the incision of an empyema** the first is usually chosen. The overlying soft parts are not thick, the interspace is wide enough, drainage is sufficient (especially if part of the seventh or eighth rib be resected), and this site is free from the objection that the angle of the scapula overlaps the seventh and eighth ribs, unless the arm is raised.

Outline of the heart. Its relation to the chest-wall.—The upper limit of the heart (base) will be defined by a line crossing the sternum a little above the upper border of the third costal cartilage, reaching about 1.2 cm. ($\frac{1}{2}$ in.) to the right and about 2.5 cm. (1 in.) to the left of the sternum. Its apex point is in the fifth space, 3.7 cm. ($1\frac{1}{2}$ in.) below the male left nipple, and 2.5 cm. (1 in.) to the medial side. This point will be at 7.5 cm. (3 in.) from the left border of the sternum. The right border (right atrium) will be given by a line, slightly convex laterally, drawn from the right extremity of the upper border to the right sixth chondro-sternal joint. If another line, slightly convex upward, be drawn onward from this point across the last piece of the sternum, just above the xiphoid cartilage, to the apex, it will give the lower border (margo acutus of right ventricle), which rests on the central tendon of the diaphragm. The left border (margo obtusus of left ventricle) will be given by a line, convex to the left, passing from the left extremity of the upper border to the apex, medial to the nipple-line. This line should be 7.5 cm. (3 in.) from the middle of the sternum at the level of the fourth costal cartilage. The base of the heart is opposite four of the thoracic vertebræ, viz., the sixth, seventh, eighth, and ninth. The apex and anterior or costo-sternal surface have been mentioned. The inferior or diaphragmatic surface (chiefly left atrium and left ventricle) rests upon the diaphragm, mainly the central tendon, to which the intervening pericardium is connected, and is thus adjacent to the liver and a small portion of the stomach.

If a circle 5 cm. (2 in.) in diameter be described around a point midway between the left nipple and the lower end of the gladiolus, it will define with sufficient accuracy for practical purposes that part of the heart which lies immediately behind the chest wall, and which is uncovered by lung and (in part) by pleura. (Latham.)

The valves.—The **pulmonary valves** (the highest and most superficial) lie, in front of the aortic, behind the third left chondro-sternal joint, and opposite to the upper border of the third costal cartilage. The **aortic valves** lie behind and a little below these, opposite to the medial end of the third intercostal space, and on a level with the lower border of the third left costal cartilage. The **atrio-ventricular openings** lie at a somewhat lower level than that of the aortic and pulmonary. Thus the **tricuspid valves** lie behind the middle of the sternum at the level of the fourth intercostal space; and the **mitral valves**, the most deeply placed of all, lie a little to the left of these, behind the left edge of the sternum and the fourth left costal cartilage (fig. 1107; also cf. fig. 437).

'Thus these valves are so situated that the mouth of an ordinary-sized stethoscope will cover a portion of them all, if placed over the juncture of the third intercostal space, on the left side, with the sternum. All are covered by a thin layer of lung; therefore we hear their action better when the breathing is for a moment suspended.' (Holden.)

The pericardium.—This fibro-serous sac, occupying the middle mediastinum, is triangular in shape, with the apex upward. Here its fibrous layer gives investment to the large vessels, except the inferior cava. It is also continuous with the deep cervical fascia. The base, connected with the diaphragm, has been referred to above. In front an area of variable size (fig. 1107), owing to the divergence of the left pleura, is in contact with the left half of the lower part of the sternum, and more or less of the medial ends of the fourth, fifth, and sixth costal cartilages, here forming the posterior boundary of the anterior mediastinum. Behind, the pericardium is the anterior boundary of the posterior mediastinum, and is in close contact with the œsophagus and aorta.

Paracentesis of pericardium.—While the seat of election must here remain an open question, each case requiring a decision for itself, the one most suitable on the whole is the fifth left space, about 2.5 cm. (1 in.) from the sternum, so as to avoid injury to the internal mammary artery and the pleura, of which the line of reflection has been shown to vary.

In **incision of the pericardium** to establish free drainage, a portion of the fifth or sixth left costal cartilage should be carefully resected, the internal mammary artery tied, the transversus thoracis (triangularis sterni) scratched through, and the pleural reflexion pushed aside.

Relation of vessels to the wall of the thorax.—**Aortic arch.**—The ascending part of the aorta reaches from a spot behind the sternum, a little to the left of the centre, on a level with the third left costal cartilage, to the upper border of the second right cartilage; thus it passes upward, backward, and to the right, and is about 5 cm. (2 in.) long. The transverse part then crosses backward to the left behind the sternum (the highest part of the arch being about 2.5 cm. (1 in.) below the notch), reaching from the second right costal cartilage to the lower border of the fourth thoracic vertebra on the left side. This part recedes from the surface, and, with the next, cannot be marked out on the surface. The third, or descending part, the shortest of the three, reaches from the lower border of the fourth to that of the fifth thoracic vertebra.

Fig. 1104 will remind the reader of many of the pressure symptoms which may accompany an **aneurysm of the aortic arch**; e. g., pressure on the left innominate vein, the three large arteries, trachea, and left bronchus, recurrent nerve, œsophagus, and thoracic duct. In **aneurysm of the thoracic aorta**, pain, usually unilateral, referred to the corresponding intercostal nerves, is a common pressure symptom.

The pulmonary artery lies behind the left side of the sternum and its junction with the second and third costal cartilages.

Innominate artery.—A line drawn from the top of the arch, about 2.5 cm. (1 in.) below the sternal notch, and close to the centre, to the right sterno-clavicular joint, will give the line of this vessel.

Left common carotid.—This vessel will be denoted by a line somewhat similar to the above, passing from the level of the arch a little to the left of the last starting-point to the left sterno-clavicular joint.

Left subclavian artery.—A line from the end of the transverse arch, behind the left of the sternum, straight upward to the clavicle, delineates the vertical thoracic course of the long left subclavian artery; its thoracic portion lies behind the left carotid.

Innominate veins.—The **left**, 7.5 cm. (3 in.) long, extends very obliquely from the left sterno-clavicular joint, behind the upper part of the manubrium, to a point 1.2 cm. ($\frac{1}{2}$ in.) to the right of the sternum, on the lower border of the first right costal cartilage. The **right**, about 2.5 cm. (1 in.) long, descends almost vertically to the above point from the right sterno-clavicular joint.

Venæ cavæ.—The **superior** descends from the point above given for the meeting of the innominate veins in the first intercostal space, close to the sternum, and perforates the right atrium on a level with the third costal cartilage. The **inferior vena cava.**—The opening of this vein into the right atrium lies under the middle of the fifth right interspace and the adjacent part of the sternum.

The œsophagus.—The relations of this tube in its cervical and thoracic portions are most important, e.g., to the trachea and left bronchus; the vagi and left recurrent nerve; the pleuræ, left above and right below, aorta, and pericardium. Its lymphatics go below into the posterior mediastinal and superior gastric nodes; above into the lower deep cervical nodes, a point sometimes diagnostic in malignant disease.

The lumen of the œsophagus is narrowed at three points:—(1) and best marked at the cricoid cartilage, (2) where it is crossed by the left bronchus, (3) as it passes through the diaphragm. The tube, 25 to 27 cm. (10 to 11 in.) long, extends from the sixth cervical to the lower border of the tenth thoracic vertebra. In an adult, the distance from the incisor teeth to the cricoid is about 15 cm. (6 in.); an additional 7.5 cm. (3 in.) gives the level of the crossing of the left bronchus, while from the teeth to the opening in the diaphragm would be from 41 to 43 cm. (16 to 17 in.). To expose the tube in the neck an incision is made on the left side, much as for the higher ligature of the common carotid, but carried lower down. The depressors of the hyoid being drawn medially or divided, the pretracheal fascia is opened, which allows of the overlapping thyreoid and trachea being displaced medially, while the carotid sheath is retracted laterally. The tracheal rings are the best guide to the œsophagus. The recurrent nerve must be avoided.

THE ABDOMEN

The regions and subdivisions will first be considered, the abdominal wall next, and finally the abdominal cavity, including the peritoneum and the various organs.

Subdivision of the abdominal cavity.—Certain arbitrary horizontal and vertical planes, represented by lines drawn on the ventral surface, are used to subdivide the abdomen for topographical purposes (fig. 898). A. **Horizontal planes.** (1) *Infracostal* through the lower margins of the tenth costal cartilages (the lowest part of the costal margin). This plane crosses the body of the third lumbar vertebra. (2) *Intertubercular*, passing through the tubercles, prominent points of the iliac crests, which are situated about 5 cm. (2 in.) behind the anterior superior spines. This plane crosses the body of the fifth lumbar vertebra. B. **Vertical planes.** (1) *Median vertical,* drawn upward in the middle line from the symphysis pubis. (2) *Lateral vertical,* drawn upward on each side parallel to the former, from a point midway between the anterior superior iliac spine and the symphysis pubis.

These lateral lines if prolonged upward into the thorax pass rather more than 2.5 cm. (1 in.) to the medial side of the male nipple and meet the clavicle a little medial to its mid-point.

According to the BNA system, the lateral vertical lines are slightly curved, extending upward from the pubic tubercle on each side along the lateral margin of the rectus muscle (corresponding to the linea semilunaris).

The infracostal and intertubercular planes, with the two lateral vertical planes that intersect them divide the abdomen into nine regions:—three **median,** viz., the **epigastric, umbilical,** and **hypogastric** and on each side three **lateral,** viz., **hypochondriac, lumbar,** and **iliac** (fig. 898).

Another transverse plane of practical importance, though we do not use it as a boundary of the abdominal subdivisions, is represented by Addison's **transpyloric line,** drawn horizontally through a point midway between the umbilicus and the sterno-xiphoid junction (or midway between the symphysis pubis and supra-sternal notch). It crosses the spine at the level of the first lumbar vertebra. It must be noted that the pylorus only lies in this plane during life when the subject is in the horizontal position. On assuming the upright position the pylorus falls at least one vertebra lower. **The sterno-xiphoid plane,** drawn horizontally through the junction of the body of the sternum with the xiphoid, cuts the spine at the disc between the ninth and tenth thoracic vertebræ, and the **umbilical plane,** passing through the umbilicus, crosses the disc between the third and fourth lumbar vertebræ (though in corpulent subjects it is somewhat lower).

The abdominal wall. Bony and muscular landmarks.—The **linea alba** forms a perceptible groove in the middle line from the xiphoid cartilage to below the umbilicus. It is a band of interlacing fibres, mostly crossing each other at right angles, that forms the main insertion of the transversus and oblique muscles, and stretches between the two recti muscles from xiphoid cartilage to symphysis. It is on the average 1.2 cm. ($\frac{1}{2}$ in.) wide above the umbilicus. Below the umbilicus it narrows rapidly and becomes merely a thin fibrous septum between the two recti, which in this position lie close together.

In its broad supra-umbilical portion, small hernial protrusions of subperitoneal fat often force their way through interstices in the linea alba, and true peritoneal sacs may be drawn through after them. The linea alba is not very vascular, and hence was at one time the favourite site of incisions in opening the abdominal cavity. Since the resulting scar is weak and yielding, however, it is now more customary to make vertical incisions through the rectus sheath, to one side of the middle line, where the abdominal wall can be sutured in layers, and an incisional hernia prevented.

The umbilicus lies in the linea alba rather below its centre. It is somewhat prone to hernia formation (p. 1402) and is occasionally the site of congenital fistulæ, which may originate in a Meckel's diverticulum (p. 1376) or a patent urachus.

When the recti are thrown into contraction the **linea semilunaris** on each side is made evident as a groove, extending with a slight lateral convexity from the tip of the ninth costal cartilage, where the lateral vertical line meets the thoracic margin, to the pubic tubercle.

The contraction of the recti muscles also shows up the three lineæ transversæ, fibrous intersections adherent to the anterior layer of the sheath of the rectus, which cross the substance of the muscle (1) at the umbilicus, (2) at the tip of the xiphoid, and (3) midway between the former two. A tonic contraction of one or both recti localised to one of these segments occasionally gives rise to the "phantom" tumors which occur in some hysterical cases.

The linea semilunaris shares the disadvantages of the linea alba as a site for incisions, and there is the further danger of injury to the nerve supply of the rectus, which may involve a diffuse bulge of the atrophied muscle.

In tapping the bladder above the pubes, the trocar should be introduced immediately above the pubes and driven backward and a little downward. In this operation, and in suprapubic cystotomy, the retro-pubic space or **cavum Retzii** is opened. This is bounded in front by the pubes and superior fascia of the urogenital diaphragm, behind by the anterior surface of the bladder. Below are the true ligaments of this viscus. The space contains fatty tissue and veins, increasing in size with the advance of life. If about ten ounces of fluid are injected into the bladder, the peritoneum will be raised sufficiently to allow of a three-inch incision being made between the recti and pyramidales immediately above the pubes. The transversalis fascia is thicker below, and is often separated from the linea alba by fat, which must not be mistaken for the extra-peritoneal layer. The peritoneal reflexion is loosely connected to the bladder and can always be peeled upward.

A transverse line drawn from one anterior superior iliac spine to the other crosses at about the level of the top of the promontory of the sacrum. Such a line will always show whether the pelvis is horizontal or not. (Holden.)

The **inguinal (Poupart's) ligament** corresponds to a line drawn with a slight curve downward between the anterior superior iliac spine and the pubic tubercle. The first of these bony prominences corresponds to the starting-point of the above ligament, the attachment of the fascia lata to the ilium, the meeting of the fleshy and aponeurotic parts of the external oblique (denoted by a line drawn upward from this spine to the ninth costal cartilage, or often a little anteriorly to these points), the point of emergence of the lateral cutaneous nerve of the thigh, and part of the origins of the internal oblique, transversus, and tensor fasciæ latæ.

The pubic tubercle marks the lateral pillar (inferior crus) of the **subcutaneous inguinal (external abdominal) ring,** the mouth of which corresponds to the crest of the pubes lying between the tubercle and the symphysis. The neck of an inguinal hernia is above the tubercle and Poupart's ligament; that of a femoral hernia below and lateral to the tubercle, and below the same ligament. The ring, and especially its lateral pillar, can easily be felt by invaginating the scrotal skin with a finger, and pushing upward and laterally. In a female patient, if the thigh be abducted, the tense tendon of the adductor longus will lead up to the site of the ring. The **abdominal inguinal (internal abdominal) ring** is situated about 1.2 cm. ($\frac{1}{2}$ in.) above the centre of Poupart's ligament; oval in shape, and nearly vertical in direction, it has the arching fibres of the transversus above it, and to its medial side the inferior epigastric artery, lying behind the spermatic cord. The pulsations of this vessel here guide the finger in the insertion of the uppermost deep sutures in radical cure of hernia. The **canal** runs obliquely downward and forward between the two rings. In the adult it is about 3.7 cm. ($1\frac{1}{2}$ in.) long, but in early life, and in adults with a large hernia dragging upon the parts, the two rings are much nearer, and may be one behind the other. For the anatomy of inguinal hernia see p. 1304.

Vessels in the abdominal wall.—The three superficial branches of the common femoral, the external pudic, epigastric, and circumflex iliac, supply the lowest part of the abdominal wall and the adjacent groin and genitals. The others that have to be remembered are the inferior epigastrics and the epigastric branch of the internal mammary, the deep circumflex iliacs, the last two intercostals, and the abdominal branches of the lumbar arteries.

Of these, the inferior epigastric is the most important; its course will be marked out by a line drawn from a point just medial to the centre of the inguinal ligament, upward and medially to the medial side of the abdominal ring, and thence to a point about midway between the pubes and umbilicus, forming the lateral boundary of Hesselbach's triangle (fig. 1121). Here the vessel, which at first lies between the peritoneum and fascia transversalis, perforates the latter and, passing over the semicircular line (fold of Douglas) enters the sheath of the rectus. It then runs upward, closely applied to the back of that muscle, and, a little above the level of the umbilicus, divides into branches which anastomose with the epigastric branch of the internal mammary.

One **superficial vein in the abdominal wall** needs especial mention, the thoraco-epigastric, joining the veins of the chest, e. g., the long thoracic above with, the superficial epigastric below. Its valves directing the blood downward below and upward above (Stiles) may be rendered incompetent when this vessel is enlarged, as in interference with the portal vein, with which it communicates by a vein in the round ligament, or in blocking of the inferior vena cava.

Lymphatics.—It is sufficiently correct to say here that those above the umbilical line go to the axillary, and those below that line to the inguinal nodes.

Nerves.—The lower seven intercostals and the ilio-hypogastric and ilio-inguinal supply the abdominal wall. The sixth and seventh intercostals supply the skin over the upper epigastrium; the eighth, the area of the middle linea transversa; the tenth, that of the umbilicus; the last thoracic, ilio-inguinal and ilio-hypogastric, the region above Poupart's ligament, and that of the pubes. The ilio-hypogastric supplies the skin over the subcutaneous inguinal (external abdominal) ring; the ilio-inguinal that over the cord and scrotum. The last thoracic and ilio-hypogastric cross the iliac crest to supply the skin of the buttock.

The diaphragm.—The upper limit of the diaphragm rises to the following levels in full expiration: Its central tendon to about the lower end of the body of the sternum, or the seventh chondro-sternal joint; the right half to the fifth rib, or about 1 cm. ($\frac{1}{2}$ in.) below the nipple; the left half not rising quite so high, i. e., to the fifth space, or 2.5 cm. (1 in.) below the nipple.

Topographical relations of abdominal viscera.—These will include the peritoneum, liver and bile passages, stomach, spleen, pancreas, intestines, kidneys and ureters, and large abdominal vessels.

The peritoneal spaces.—The peritoneum presents certain potential spaces, determined by its various reflections from the parietes and abdominal viscera. In these spaces collections of fluid such as abscesses or extravasations from hollow viscera or blood vessels may collect and become shut off by adhesions or overflow in various directions into neighbouring spaces. The transverse mesocolon and great omentum together form a shelf transversely placed, which divides the greater sac into two main divisions—supra-omental and infra-omental.

The **supra-omental region**, in which the various forms of subphrenic abscess are found, contains the following fossæ (Barnard).* (1) *Right subphrenic*, between the right lobe of the liver and right cupola of the diaphragm, bounded toward the median line by the falciform ligament, and behind by the coronary ligament. It communicates below with (2) the *subhepatic fossa* or right renal pouch (Morison), which is bounded above by the visceral surface of the liver, and below by the mesocolic shelf and right kidney. It extends from the right lateral abdominal wall, its most capacious part, across the median line under the left lobe of the liver, and on its posterior aspect lie the upper pole of the right kidney, epiploic foramen, and anterior surface of small omentum. (3) The **left subphrenic**, also known as the anterior perigastric fossa, lies between the left dome of the diaphragm above, and the left lobe of liver, stomach, spleen and omentum below. It is bounded on the right by the falciform ligament which lies somewhat to the right of the median line. (4) The **omental bursa** may be regarded as a diverticulum from the subhepatic fossa with which it communicates by the epiploic foramen. Abscesses in this sac are rare, but occasionally laceration of the pancreas which is closely related to it behind gives rise to a collection of pancreatic juice and blood in the lesser sac, known as a pancreatic pseudo-cyst (Jordan Lloyd).

The **infra-omental region** is subdivided in its abdominal part into (1) **right** and (2) **left compartments** by the attachment of the root of the mesentery to the spine, descending from the duodeno-jejunal flexure downward into the right iliac fossa. These fossæ communicate with the supra-omental regions in the neighbourhood of the hepatic and splenic flexures of the colon respectively, and below with (3) **the pelvis.** The deepest level of the peritoneum lining the pelvis constitutes in the male the recto-vesical, and in the female the recto-vaginal fossa (pouch of Douglas).

It should be noted that with a patient in the supine position, owing to the contour of the psoas muscles and the anterior convexity of the lumbar spine, any fluid above the pelvic brim will tend to gravitate into the subphrenic spaces across the flexures of the colon which lie far back in the loins. This is undesirable in view of the great absorbing power of the subphrenic lymphatics, and may be obviated by propping the patient in a half-sitting position.

* Barnard, H. L., Brit. Med. Journal, Feb. 15, 1908.

Viscera behind the linea alba.—From above downward there are the following:—(1) **Above the umbilicus**—the left lobe of the liver, the stomach, the transverse colon, part of the great omentum, the pancreas, and cœliac (solar) plexus. (2) **Below the umbilicus**—the rest of the great omentum, covering in the small intestines and their mesentery. In the child, the bladder occupies a partly abdominal position; and in the adult, the same viscus, if distended, will rise out of the pelvis and displace the above structures, raising the peritoneum until, if distended half way to the umbilicus, there is an area of nearly 5 cm. (2 in.) safe for operations above the symphysis. The gravid uterus also rises behind the linea alba.

The liver (figs. 914, 941, and 1125).—In the erect position, the anterior thin margin of the liver projects about 1 cm. ($\frac{1}{2}$ in.) below the costal cartilages, but can only be made out with difficulty in this position. It may also be displaced downward by pleuritic effusion or tight lacing. The liver is also, proportionately, much larger in small children.

Of the three more accessible surfaces, *the right lateral* is opposite the seventh to the eleventh intercostal arches, separated from them by the pleura, the thin base of the lung, and the diaphragm. The *superior* surface is accurately fitted with its right and left portions into the hollows of the diaphragm, a slightly depressed area intervening which corresponds to the central tendon. Its level corresponds to that of the diaphragm given above. On the left side, in the adult, the limit of the left lobe will be in the fifth interspace, about 7.5 cm. (3 in.) from the sternum. The *anterior* surface is in contact with the diaphragm, costal arches, and, between them, the xiphoid cartilage, and, below, with the abdominal wall. Both the superior and anterior surfaces are subdivided by the falciform ligament, an important point in subphrenic suppuration. In the right hypochondrium the anterior margin corresponds to the lower margin of the thorax; but in the epigastric region, running obliquely across from the ninth right to the eighth left costal cartilage, it crosses the middle line about a hand's breadth below the sterno-xiphoid articulation (Godlee), or half-way between the sterno-xiphoid junction and umbilicus, i.e., in the transpyloric line (fig. 914). Behind, the anterior margin, following the right lateral surface within the costal arches, crosses the last rib toward the level of the eleventh thoracic spine. In the anterior border, a little to the right of the median vertical plane, is the umbilical notch, where the falciform and round ligaments meet. Still further to the right, and just to the left of the mid-Poupart plane, is the fundus of the gall-bladder.

Gall-bladder and bile passages.—The fundus of the gall-bladder, situated in a fossa on the under surface of the right lobe of the liver, and having the quadrate lobe to its left, lies opposite to the right ninth costal cartilage, close to the lateral edge of the rectus. This point corresponds to the site of intersection of the lateral vertical and transpyloric lines. It is in contact with the hepatic flexure of the colon and the first piece of the duodenum, into either of which, but particularly the latter, large gall-stones impacted in the neck of the gall-bladder occasionally ulcerate. A distended gall-bladder as it enlarges tends to take a line obliquely from the above point where it emerges from under the costal margin toward the umbilicus.

The long axis of the gall-bladder is directed from the fundus backward and upward. The cystic duct runs from the neck downward and forward in the gastro-hepatic omentum, and so forms an acute angle with the gall-bladder. A spiral fold of mucous membrane at the junction of the two, which fulfils the function of keeping the lumen open for the flow of bile, adds to the difficulty of passing a bougie from the gall-bladder down into the common duct.

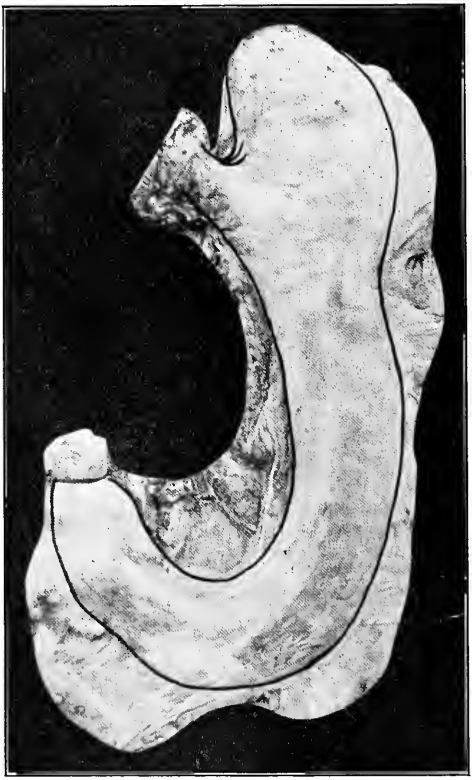
The hepatic and cystic ducts join in the right free margin of the gastro-hepatic omentum to form the **common bile-duct**, 7.5 cm. (3 in.) in length, which as it runs down to open into the duodenum presents four distinct stages. (1) It first lies in the free edge of lesser omentum in front of the epiploic foramen, with the hepatic artery to the medial side, and the portal vein behind them both. (2) Behind the first part of the duodenum with the gastro-duodenal artery accompanying it. (3) In a deep groove in the head of the pancreas, between that gland and the posterior aspect of the second part of the duodenum. The pancreatic tissue surrounds it completely in 75 per cent. of cases, (Bunger) hence the jaundice that occurs in chronic interstitial pancreatitis. (4) Piercing the muscular wall of the duodenum obliquely it ends by joining the main duct of the pancreas at the ampulla of Vater and opening into the second part of the duodenum by a common orifice. This orifice, situated on the postero-medial aspect of the gut, rather below the centre of the second portion, is raised on a small papilla and is narrower than the lumen of the common duct.

The stomach.—The study of this organ by rendering its contents opaque with bismuth salts and projecting its shadow by X-rays on a fluorescent screen, has greatly modified the conception of its shape and position formed from post-mortem and operative observations. Examined post-mortem, or at operations under general anæsthesia it forms a flaccid sac with its long axis directed from the fundus obliquely downward, forward, and to the right. Seen under X-rays, with the patient standing upright, the cardiac portion (the fundus and body together) is vertical, and the smaller pyloric portion is directed backward and to the right and slightly upward (fig. 1125). The most fixed point is the cardiac orifice.

The **cardiac orifice** lies under the seventh left costal cartilage 2 cm. (¾ in.) from the sterno-xiphoid junction at a depth of about 10 cm. (4 in.) from the surface. Behind, this point corresponds to the tenth thoracic vertebra.

The **pyloric orifice** lies in the transpyloric plane when the patient is recumbent, but when the patient is standing it falls to the level of the second or third lumbar vertebra, or lower still

Fig. 1108.—Photograph of an Empty Stomach. (J. S. B. Stopford.)



when any transient faintness or nausea causes loss of muscular tone (Barclay). The pylorus is slightly to the right of the middle line in the empty stomach. As the stomach fills it descends farther and moves a little farther to the right. The *lesser curvature* presents a definite notch at the junction of the cardiac and pyloric portions of the stomach—the *incisura angularis*. The *greater curvature* reaches the umbilical plane in the erect posture, even when the stomach is empty. When the viscus is full this curvature lies distinctly below this plane, being lower in women than in men (Hertz). The *pyloric portion* of the full stomach is directed backward and a little upward, as the distended pyloric vestibule moves further to the right than the pyloric orifice and lies on an anterior plane. In the recumbent posture the greater curvature lies above the umbilical plane, even when moderately distended, and the stomach is more obliquely placed. The *fundus* invariably contains gas, even when the stomach contains no food, in which case the organ forms a contracted J-shaped tube (fig. 1108). In extreme distention the left dome of the diaphragm is so pushed up by the fundus that it lies at a level as high as or even higher than the right dome (Hertz). The pressure thus exerted on the heart accounts for the dyspnœa and cardiac pain so often associated with flatulence. The position of the pyloric sphincter is shown on the outer surface by a very constant venous ring running toward both lesser and greater curvatures in the subserous layer at right angles to the long axis of the pyloric canal (Moynihan).

In connection with the extravasation of contents that results from perforating ulcers of the stomach, a knowledge of the subphrenic peritoneal fossæ is important (p. 1372). Perforation is rare on the posterior surface since it is less mobile than the anterior, and protective adhesions form readily. When it does occur, extravasation into the omental bursa results, and such a perforation is exposed by turning up transverse colon and stomach and incising the transverse meso-colon. Perforation on the anterior surface usually gives rise to general peritonitis, but in the less serious cases an abscess may form localised to (1) the right subphrenic space, (2) the subhepatic fossa, or (3) the left subphrenic space, according to the situation of the ulcer on the stomach.

The spleen (fig. 1127; see also figures in Sections IX and XII).—This lies very obliquely in the left hypochondrium, its long axis corresponds closely with the line of the tenth rib. It is placed opposite the ninth, tenth, and eleventh ribs externally, being separated from these by the diaphragm; and medially it is connected with the great end of the stomach. Below, it overlaps slightly the lateral border of the left kidney (fig. 1127). Its highest point is on a level with the spine of the ninth thoracic, and its lowest with that of the eleventh thoracic vertebra. Its upper pole is distant about 3.7 ($1\frac{1}{2}$ in.) from the median plane of the body, and its lower pole about reaches the mid-axillary line on the same rib. (Godlee.) In the natural condition it cannot be felt; but if enlarged, its notched anterior margin extends downward toward the umbilicus, and is both characteristic and readily felt.

The pancreas.—The head of the pancreas lies in the hollow formed by the three parts of the duodenum, on the bodies of the second and third lumbar vertebræ. The inferior vena cava lies behind it. The neck, body, and tail of the pancreas pass obliquely to the left and slightly upward, crossing respectively the commencement of the portal vein, the aorta, and the left kidney. The root of the transverse mesocolon is attached to the anterior margin of the gland, so that its supero-anterior surface is related to the omental bursa, and its inferior surface to the greater sac. The importance of this relation in the formation of pancreatic pseudo-cysts has been referred to above.

Pancreatic ducts.—The main duct, the duct of Wirsung, opens into the common ampulla of Vater with the bile duct. This ampulla usually opens into the gut by a narrow orifice raised on a small papilla. A gall-stone impacted in the ampulla may cause a flow of bile backward along the duct of Wirsung, and so give rise to acute pancreatitis (Opie). The small accessory duct of Santorini opens into the duodenum independently about 2 cm. higher up. It often anastomoses with the larger duct in the substance of the gland.

Accessory nodules of pancreatic tissue are occasionally met with in the walls of the stomach or small intestine at different regions.

A cyst originating in the pancreas may "point" toward the anterior abdominal wall by three routes:—(1) Above the stomach through the lesser omentum; (2) between stomach and transverse colon through the great omentum; (3) below the transverse colon through the transverse mesocolon. The posterior aspect of the head of the gland, with the third part of the common bile duct may be exposed by incising the peritoneum on the lateral margin of the second part of the duodenum, and turning the gut medially toward the middle line.

Intestines. (A) **Small.**—The average length of the small intestine is about 6.85 m. ($22\frac{1}{2}$ ft.), though the length as measured *post mortem* varies considerably with the degree of contraction of the longitudinal muscular coat. The duodenum is about 25 cm. (10 in.) in length. Of the remaining portion the upper two-fifths constitute the jejunum and the lower three-fifths the ileum, though this division is quite arbitrary. Cases are recorded in which patients have survived the removal of over 5 m. (16 ft.) of small intestine.

The *first part* of the **duodenum** extends from the pylorus on the first or second lumbar vertebra, backward and to the right. It ends near the upper pole of the right kidney and on the medial side of the neck of the gall-bladder, by turning down to form the less mobile *second part*, which descends in front of the hilum of the right kidney to the level of the third lumbar vertebra. The *third part* of the duodenum crosses the body of the third lumbar vertebra horizontally in the infracostal plane, and then turns up obliquely to the left side of the spine and ends at the level of the upper border of the second lumbar vertebra in the duodeno-jejunal flexure. The first part is the most mobile, since it is covered back and front by peritoneum in the first half of its course. The second part has a peritoneal covering in front only and is devoid of it where it is crossed by the commencing transverse colon. The third part is covered by peritoneum in front except where the superior mesenteric vessels pass across it to join the commencement of the mesentery. It is probably the constricting effect of these vessels on the duodenum that gives rise to the acute dilatation of the stomach which occasionally follows abdominal operations.

The **duodeno-jejunal flexure**, which lies on the left side of the body of the second lumbar vertebra, immediately below the body of the pancreas, is held up to the right crus of the diaphragm by a band of fibro-muscular tissue known as the *suspensory ligament of Treitz*. Some of the fibres of this structure are continued onward into the root of the mesentery. It is not found in pronograde animals. The duodeno-jejunal flexure is the commonest site of traumatic rupture of the small intestine, since it is the point of union of a fixed and a freely movable portion of the gut.

In the operation of posterior gastro-enterostomy the duodeno-jejunal flexure is readily found by passing the hand along the under surface of the transverse meso-colon to the left side of the spine, the omentum and colon being turned upward. The first coil of the jejunum is anastomosed to the posterior wall of the stomach, which is exposed by making an opening in the transverse meso-colon.

In some cases the first few centimetres of the jejunum are found to be fused between the layers of the transverse meso-colon. Certain peritoneal fossæ are often found on the left side of the flexure. They may give rise to retro-peritoneal hernia and strangulation of intestine. The duodenal fossæ are described on p. 1164.

Jejunum and ileum.—The **mesentery** contains between its two peritoneal layers the superior mesenteric vessels and their intestinal branches, the superior mesenteric plexus, lacteals and many lymph nodes on their course. These nodes are frequently enlarged in abdominal tuberculosis in children (tabes mesenterica). The attached border of the mesentery may be marked out on the surface by a line drawn from just below the transpyloric plane and a little to the left of the middle line (the duodeno-jejunal flexure), which curves downward and to the right to end in the iliac fossa at the junction of the intertubercular and right lateral vertical lines (the ileo-cæcal valve).

Meckel's diverticulum which is present in about 2 per cent. of subjects (Treves) is found in the free border of the ileum 30 cm. to 1 m. (1 to 3 ft.) above the ileo-cæcal valve. It is a remains of the vitello-intestinal duct. It is usually a blind conical pouch some 6 to 9 cm. long with a free extremity, but may be attached to the umbilicus by a fibrous cord. This cord may cause acute intestinal obstruction by strangulating a coil of gut, or the diverticulum may be invaginated and form the starting-point of an intussusception.

The presence of **aggregated lymph nodules** (Peyer's patches) in the lower part of the ileum accounts for the fact that tuberculous ulcers and perforating typhoid ulcers are almost confined to this part of the gut.

Intestinal localisation.—It often happens that the surgeon wishes to ascertain roughly to what part of the small intestine a given coil presenting in a wound belongs. The variations in length of the small intestine and the considerable range of movement of the coils during peristalsis render the problem difficult, but it may be stated as a general rule that the upper third of the intestine lies in the left hypochondrium and is not usually encountered in a wound; the middle third occupies the middle part of the abdomen, and the lower third lies in the pelvis and right iliac fossa (Monks). The jejunum is thicker walled and more vascular than the ileum. The lumen steadily diminishes as we pass downward, hence foreign bodies such as gall-stones that pass through the jejunum are apt to become impacted in the lower ileum.

The most reliable indications of the level of a given coil are found, however, on inspection of the mesentery and its blood-vessels (see fig. 482 in Section V). Opposite the upper part of the bowel the mesenteric arteries are arranged in a series of large primary anastomosing loops. From these the vasa recta run to the gut 3 to 5 cm. long, straight and unbranched. Passing downward toward the lower end, the single large primary loops give place to smaller and more numerous secondary loops arranged in layers coming nearer and nearer to the bowel. Hence the vasa recta become shorter. They become also less regular and more branched, and in the lower third of the small intestine are less than 1 cm. in length. The mesenteric fat in the upper third never reaches quite to the free edge of the mensentery, so that clear transparent spaces are left near the bowel. In the lower third the fat usually occupies the whole of the mesentery right up to the intestine, and makes it thicker and more opaque.*

The average width of the mesentery, from its root at the posterior parietes to the bowel is 20 cm. (8 in.) and the longest part lies between 2 and 8 m. from the duodenum (Treves). The ileum is freely movable on a long mesentery down to the ileo-cæcal region. In some cases however a congenital fusion of the left half of the mesentery with the parietal peritoneum near the pelvic brim binds the bowel down a few inches above the ileo-cæcal valve, and has been said to give rise to symptoms of intestinal stasis. (Flint,† Gray, and Anderson.)

(B) **Large intestine. Ileo-cæcal region.**—The position of the ileo-cæcal valve may be marked on the surface by the junction of the intertubercular and right lateral vertical lines, though it is often found considerably lower. It is situated on the postero-medial aspect of the cæcum. The **cæcum,** which is the

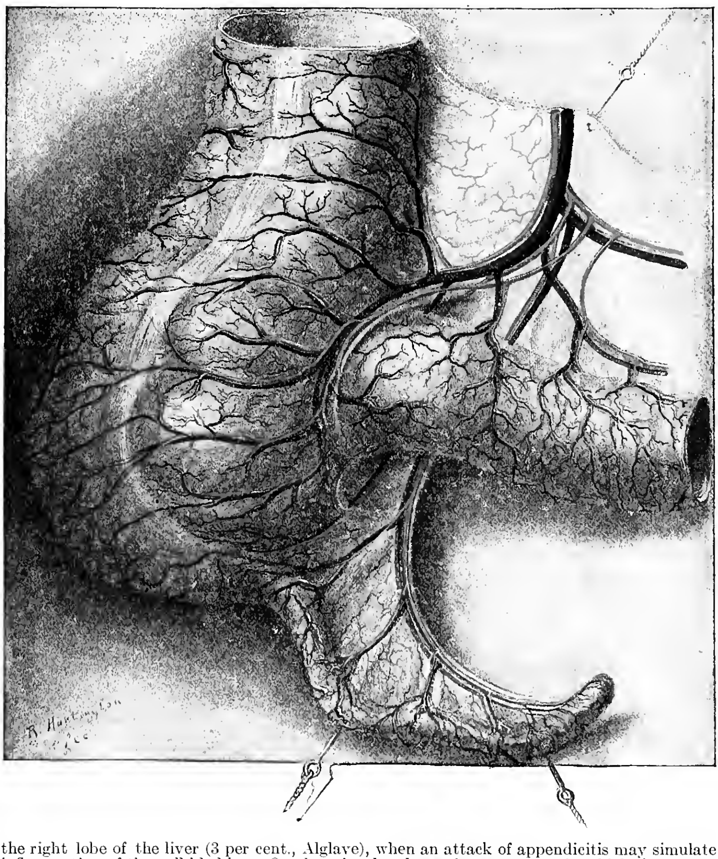
* Monks: Trans. Amer. Surg. Assoc., 1913.

† Bulletin, Johns Hopkins Hospital, Oct., 1912.

blind extremity of the colon lying below the horizontal level of the ileo-cæcal valve, is approximately 6.2 cm. ($2\frac{1}{2}$ in.) in both vertical and transverse diameters, though its size varies much with the degree of distention. It lies usually in contact with the anterior abdominal wall above the lateral half of the inguinal ligament. The orifice of the appendix (vermiform process) lies some 2 cm. below the ileo-cæcal valve. The cæcum is completely covered by peritoneum as a rule, though exceptionally its posterior surface is bound down in the right iliac fossa.

The axial rotation of the midgut and descent of the cæcum that normally take place during intra-uterine life (p. 1168) are occasionally not completed, with the result that the cæcum and appendix may be found above and to the left of the umbilicus, or less uncommonly just below

FIG. 1109.—BLOOD-VESSELS OF THE ILEO-CÆCAL REGION. (FROM KELLY).



the right lobe of the liver (3 per cent., Alglave), when an attack of appendicitis may simulate inflammation of the gall-bladder. On the other hand certain cases occur in which the cæcum descends unusually far, proceeding downward and medially until it becomes a pelvic organ whenever the bladder and rectum are empty. This pelvic position of the cæcum is found in 10 per cent. of infants (G. M. Smith).*

In the commonest form of intussusception, the ileo-cæcal valve and lower ileum are prolapsed into the colon and carried down by the force of peristalsis toward the anus. The valve in these cases forms the apex of the intussusceptum, however far it travels.

* Anat. Record, vol. 5, 1911, p. 549.

The **vermiform process** (appendix) is developed at the apex of the cæcum, and persistence of the apical appendix of fœtal type, is not uncommon. The fact that all three tæniæ coli converge at the base of the appendix is an anatomical reminder of its primitive position. The anterior tænia is of great service in operations on the appendix, since by following it down from the colon the base of the appendix can always be found. The adult position of the base of the appendix on the postero-medial aspect of the cæcum is due to the disproportionate growth of the lateral saccule of the cæcum which comes to form the apparent cæcal apex.

The appendix averages 10 cm. (4 in.) in length in the adult. The position of its base only is at all constant. It lies distinctly below McBurney's point, which is midway between the umbilicus and the right anterior superior iliac spine. This point is often the seat of greatest tenderness in appendicitis. The appendix itself may be found (1) pointing upward and to the left toward the spleen, behind the terminal ileum and mesentery; (2) hanging over the pelvic brim, in which position tenderness on rectal examination or pain on micturition results when the organ is inflamed; (3) in the retro-colic fossa; and (4) with its tip projecting to the right of the cæcum in the right lateral paracolic fossa, where it causes tenderness when inflamed close to the anterior superior iliac spine. The course and to some extent the gravity of abscesses originating in the appendix will depend upon the position the inflamed organ is occupying at the time of perforation.

The **artery of the appendix** derived from the posterior branch of the ileo-colic reaches it by running down behind the end of the ileum. It raises a fold of peritoneum called the *mesenteriolum* or *mesoappendix*. Very rarely the artery comes from the anterior branch of the ileo-colic.

The *tæniæ coli* referred to above as converging on the base of the appendix contribute its longitudinal *muscular coat*. The inner circular coat is thicker, but along the attachment of the mesenteriole certain gaps for the passage of lymph and blood-vessels occur in the muscular coats. Through these gaps infection may easily spread from the mucosa to the peritoneum (Lockwood).

The appendix is essentially a *lymph gland* and has been called the "abdominal tonsil." The lymph follicles lie in the submucosa. They are poorly developed at birth but reach their full development within the first few weeks of extra-uterine life (Berry).* Obliteration of the lumen is common but is inflammatory in origin, and not, as was once thought, a change normal in advanced age.

Pericæcal fossæ.—In addition to the mesentery of the appendix certain other folds of peritoneum are usually present at the ileo-cæcal junction: (1) the **ileo-colic** or anterior vascular fold (fig. 1109) containing the anterior branch of the ileo-colic artery; (2) the **ileo-cæcal,** or bloodless fold of Treves, running from the lower border of ileum onto the cæcum. The appendix may be in a fossa behind either of these folds. It may also be found in the **retro-colic** fossa lying behind the cæcum and commencement of ascending colon.

The **colon** is readily distinguished from the small intestine by its three longitudinal tæniæ and saccules and by the appendices epiploicæ, which are developed before birth.

The **ascending colon** runs with a slight lateral convexity upward from its junction with the cæcum to the hepatic flexure which lies under the ninth right costal cartilage at the level of the second lumbar vertebra and in contact with the anterior surface of the right kidney and the lower surface of the right lobe of the liver. It lies lateral to the right lateral vertical plane. This description is only true of an ascending colon examined by X-rays in the recumbent position. When the patient stands up, the flexure sinks to the infracostal plane (third lumbar vertebra) or even lower. As the colon ascends in the angle between the quadratus lumborum and psoas, it also passes backward at an angle of 51° with the horizontal, as may be seen in a sagittal section through the right half of the abdomen (Coffey).† The cæcum and ascending colon are distended as a rule with fluid contents and gas, and form the widest part of the colon.

The variations in the **peritoneal attachments** of the colon, which are of growing clinical importance, are explained by its mode of development (p. 1179). During intra-uterine life after rotation of the midgut round an axis formed by the superior mesenteric vessels, there is a stage in which the colon has almost assumed its permanent position in the abdomen but is still provided with a free mesocolon for both ascending and descending parts. This represents the normal condition of quadruped mammals. In the normal human individual this stage is transient, and before birth the ascending and descending colons lose their mesenteries by fusion of the posterior layers with the parietal peritoneum. Meanwhile the great omentum, formed by a bulging out of the primitive dorsal mesogastrium, fuses with the transverse colon and its mesocolon. The extent of these processes of fusion varies, particularly as far as the ascending and descending colons are concerned. Thus only 52 per cent. of adults have neither ascending nor descending mesocolons (the normal condition). A mesocolon is found on the left side in 36 per cent. of all cases and on the right side in 26 per cent. (Treves). In only a

* Journ. Anat. and Phys., vol. 35, 1900, 83.

† Surgery, Gynecology and Obstetrics, vol. 15, 1912, p. 390.

small proportion (1.8 per cent., however, does the true primitive type of ascending mesocolon persist, continuous with the mesentery of the small intestine (G. M. Smith). Such an anomaly renders the patient liable to volvulus of the ileo-cæcal region. In the common types of incomplete fusion of its peritoneal attachments the colon is inadequately adapted to the upright position and is predisposed to ptosis. A layer of peritoneum sometimes found passing downward and medially from the parietes in the right flank onto the front of the ascending colon, known as Jackson's pericolic membrane, is probably due to persistence of an early stage in the development of the great omentum, which passes to the right across the ascending colon to join with the parietal peritoneum before the descent of the cæcum is complete, and so is the most primitive agent in fixing the proximal colon back in the right loin. This membrane is usually associated with a congenitally mobile ascending colon (Morley).*

At the **hepatic flexure** the colon bends forward and to the left, leaving the front of the kidney to which it is fixed, and crossing the second part of the duodenum. In the region of the flexure three inconstant peritoneal folds are met with giving it additional attachment to the neighbouring parts, viz., (1) the *phreno-colic* and less commonly (2) the *hepato-colic* and (3) *cysto-colic* ligaments (Testut). They must not be confused with pathological adhesions acquired after birth.

The **transverse colon** is freely mobile except at its extremities. It crosses the abdomen with a convexity downward and forward, being separated from the anterior abdominal wall in the middle region by the great omentum.

At the mid-line it usually lies near the umbilical plane in the recumbent posture, considerably lower in the erect, but may be found anywhere from the infra-costal plane to the pubes, depending on the tonicity of the stomach. Its main artery, the middle colic branch of the superior mesenteric, must be avoided carefully in the operations of gastro-enterostomy and gastrectomy, since ligature of it causes gangrene of the transverse colon.

The **splenic flexure** lies far back in the left hypochondrium and is considerably higher than the hepatic flexure. It is in contact with the lower end of the spleen, and is almost invariably held firmly in position by its *phreno-colic ligament*, derived from the left extremity of the great omentum.

The **descending colon** is of narrower calibre than the preceding parts and usually is found firmly contracted and empty. It passes downward and forward in the angle between the psoas and quadratus lumborum and obliquely across to the right the iliac fossa to end in the sigmoid or pelvic colon. The lower part of the descending colon, from the iliac crest to the pelvic brim, is often termed the *iliac* colon.

In its upper part it lies in front of the convex lateral margin of the left kidney. The variations in its peritoneal attachments have been referred to above (p. 1242). The operation of lumbar colostomy, common in pre-antiseptic days, was performed through an incision in the back parallel with the last rib. The colon lies 2.5 cm. (1 in.) to the lateral side of the edge of the sacro-spinalis, between the twelfth rib and iliac crest. The occurrence of a mesocolon here was a common source of difficulty in gaining access to the bowel without opening the peritoneum.

The **pelvic colon** (also known as the *sigmoid* or omega loop (Treves), is almost as long as the transverse colon, and forms a loop, the two ends of which, at the pelvic brim and at the front of the third sacral vertebra respectively, are placed somewhat closely together. The loop is thus anatomically predisposed to axial rotation, and is the commonest seat of volvulus in the whole intestinal tract.

On the left and inferior aspect of the pelvic mesocolon near its base, a small peritoneal fossa (*intersigmoid*) is usually found in the angle formed by the root of the mesocolon and the parietal peritoneum. It occasionally contains an internal hernia which may become strangulated.

The upper part of the pelvic colon is frequently brought out and opened through an incision in the left iliac region to form an artificial anus in cases of inoperable growth of the rectum.

In advanced life, and in the chronically constipated, certain **diverticula** of mucous membrane are occasionally met with which project through the vascular gaps of the muscular coat into the bases of the appendices epiploicæ in this region, and also between the layers of the pelvic mesocolon. They often contain fæcal concretions and may become inflamed or even perforate, forming an abscess in the left iliac fossa.†

The junction of pelvic colon and rectum opposite the third sacral vertebra forms a more or less acute angle and constitutes the narrowest part of the colon. It is a frequent site of stricture.

The kidneys.—These lie at the back of the abdominal cavity so deeply in the hypochondriac and epigastric region as to be beyond palpation in most individuals, unless enlarged or unduly mobile. The lower end of the right being slightly lower than its fellow, encroaches in health upon the lumbar and umbilical regions, and may be palpable on deep inspiration in spare subjects. These

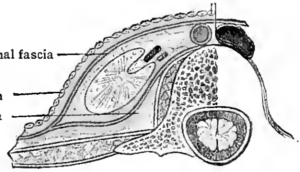
* Lancet. Dec., 1913.

† McGrath: Surgery, Gynecology and Obstetrics, vol. 15, 1912, 429.

organs lie much higher and nearer to the vertebræ than is usually supposed to be the case, the upper two-thirds of the right and all the left kidney being behind the ribs. Relatively to the vertebræ, the kidneys lie along the sides of the last thoracic and the first three lumbar.

To mark them in from the front the following points should be noted: The upper extremity of the right should reach as high up as the seventh costal cartilage, the left up to the sixth, on either side close to the costo-chondral and inter-chondral junctions. This level will correspond to one half way between the sterno-xiphoid and transpyloric lines. The lower end,

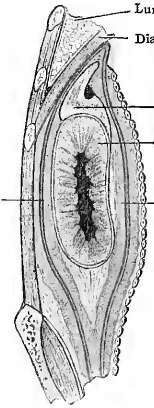
FIG. 1110.—RENAL FASCIA, AS SEEN IN CROSS-SECTION.



about 11 cm. (4½ in.) below this point, would be opposite to the subcostal line; that of the right kidney is usually lower, and may encroach upon the umbilical line. For practical purposes the hilus is opposite a point on the anterior abdominal wall, a finger's breadth medial to the tip of the ninth costal cartilage (Stiles), or the junction of the transpyloric and lateral vertical lines. The importance of the relation of the last rib has been mentioned at p. 1245. The lateral vertical line has one-third of the kidney to its lateral side, and two-thirds to its medial side. The shortest distance between the two kidneys, obliquely placed so as to be closer above, 'at the upper part of their medial borders' (Thane and Godlee), measures about 6.2 cm. (2½ in.).

On the posterior surface of the body the kidney's boundaries are indicated by the following:—(1) A line parallel with, and 2.5 cm. (1 in.) from, the mid-line, between the lower edge of the tip

FIG. 1111.—RENAL FASCIA, AS SEEN IN SAGITTAL SECTION.



of the spinous process of the eleventh thoracic and the lower edge of the spinous process of the third lumbar vertebra; (2) and (3) lines drawn from the top and bottom of this line laterally, at right angles to it, for 7 cm. (2¾ in.); (4) a line parallel to the first, and connecting the extremities of (2) and (3). Within this parallelogram the kidney lies (Morris).

The **chief relations of the kidneys** are:—**posteriorly**—quadratus lumborum, psoas, diaphragm, last thoracic, ilio-hypogastric, and ilio-inguinal nerves. The twelfth rib lies behind both, the right, as a rule, not reaching above the upper border. The left often reaches the eleventh rib. The pleural reflection usually crosses the twelfth rib obliquely reaching below its neck. **Anteriorly**—The liver, right colic flexure and second part of the duodenum (figs. 956 and 1009), on the right side. The liver, and stomach above, the body of the pancreas and spleen over the centre, and the descending colon over the lower part of the left kidney.

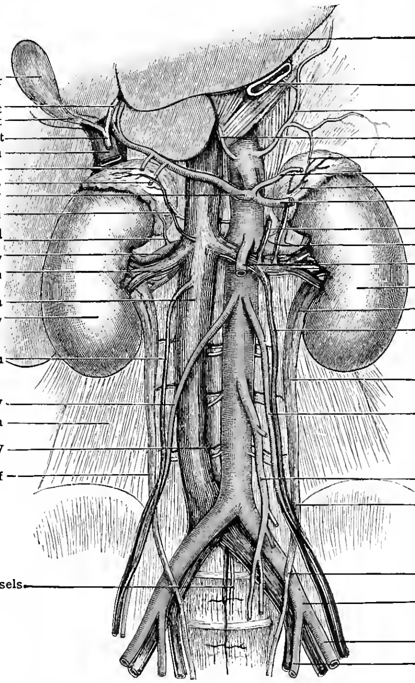
The attachments of the specialised fibrous sheets known as the **renal fascia** are shown in figs. 1110 and 1111.

The anterior and posterior layers are seen to be continuous above and laterally. Medially and below they remain separate and it is in this direction that the abnormally movable kidney travels. The fatty tissue between the kidney and the renal fascia is known as the perinephric fat; that outside the fascia is the paranephric fat.

The kidneys are maintained in position by (1) the vascular pedicle; (2) fatty capsule and fascia; (3) above all by the intra-abdominal pressure.

Failure to ascend during development from its original position near the pelvic brim to its normal level accounts for certain cases of *movable kidney* of congenital origin. In these cases

Fig. 1112.—The Abdominal Aorta and Vena Cava Inferior.



the renal artery may take origin from the common iliac artery. An *accessory renal artery* running into the lower end of the kidney from the aorta may cause kinking of the ureter and is a not uncommon cause of hydronephrosis.

The suprarenal glands are not so firmly attached to the kidneys as to the diaphragm; hence they are not encountered in operations for movable kidney and are not removed in nephrectomy.

Brödel has shown that incisions into the kidney should be made rather behind its convex border (Brödel's bloodless line). Occasionally fusion of the lower poles occurs during development across the middle line of the body, and a single *horseshoe kidney* results, with double ureter and vascular supply.

The ureter.—On an average 30 cm. (12 in). long, this tube descends almost vertically in its abdominal course on the psoas muscle. It is crossed obliquely by the spermatic or ovarian vessels. It crosses the brim of the pelvis just in front of the bifurcation of the common iliac, and descends on the side wall of the pelvis in front of the hypogastric artery.

The abdominal part of the ureter may be exposed extraperitoneally by an extension forward of the usual lumbar renal incision. It is found lying between peritoneum and psoas 3.7 cm. ($1\frac{1}{2}$ in.) from the middle line and when the peritoneum is stripped from the posterior abdominal wall the ureter is invariably carried with it.

Aorta and iliac arteries.—The aorta enters the abdomen opposite the last thoracic vertebra, a point 12 to 15 cm. (5 to 6 in.) above the umbilicus, or rather above the mid-point between the infrasternal depression and the umbilicus (Thane and Godlee), and thence, lying to the left of the mid-line, divides into the two common iliacs opposite the disc between the third and fourth lumbar vertebræ, or opposite the body of the fourth lumbar vertebra. This point is about 2.5 cm. (1 in.) below and to the left of the umbilicus, and on a level with a line drawn across the highest part of the iliac crest. A line drawn from this point, with a slight curve laterally, to just medial to the centre of Poupart's ligament, will give the line of the iliac arteries; the upper third of this line giving the average length of the common iliac. The relation of the common iliac veins is shown in fig. 1112. The **right,** much shorter than its fellow, lies at first behind and then somewhat lateral to its artery. The **left** is at first to the medial side of its artery, and then behind the right. At the upper part of the fifth lumbar vertebra behind and lateral to the right artery, the vena cava begins.

The site of **some of the branches of the aorta** may be thus approximately remembered as follows: The **cœliac artery** is given off immediately after the aorta has perforated the diaphragm; directly below this is the **superior mesenteric artery.** About 2.5 cm. (1 in.) lower down, or 7.5 cm. (3 in.) above the umbilicus, the **renal arteries** are given off. About 2.5 cm. (1 in.) above the umbilicus would be the level of the **inferior mesenteric artery.** The relation of the above vessels to the transpyloric line (p. 1153) is as follows: (Stiles.) The cœliac artery is two fingers' breadth, the superior mesenteric one, above the line, the renal arteries are a finger's breadth below it. The origin of the inferior mesenteric is midway between the transpyloric and intertubercular lines.

Collateral circulation after ligature of the common iliac.—The chief vessels here are:—

ABOVE.		BELOW.
Pubic branch of inferior epigastric	with	Pubic branch of obturator.
Internal mammary and lower intercostals	with	Inferior epigastric.
Lumbar	with	Ilio-lumbar and circumflex iliac.
Middle sacral	with	Lateral sacral and superior gluteal.
Superior hæmorrhoidal	with	Inferior and middle hæmorrhoidal.
Ovarian	with	Uterine

Collateral circulation after ligature of the external iliac:—

Internal mammary, lower intercostals, and lumbar.	with	Inferior epigastric.
Ilio-lumbar, lumbar, and gluteal	with	Deep circumflex iliac.
Internal and external circumflex	with	Superior and inferior gluteal (sciatic).
Perforating branches of profunda	with	Inferior gluteal (comes nervi ischiadici).
Circumflex and epigastric	with	Obturator.
External pudic	with	Internal pudic.

Collateral circulation after ligature of the internal iliac:—

Branches of profunda	with	Inferior gluteal (sciatic).
Inferior mesenteric	with	Hæmorrhoidal arteries.
Vessel of opposite side	with	Pubic branch of obturator.
Branches of opposite side	with	Branches of pudic.
Superior and inferior gluteal (sciatic)	with	Circumflex and perforating of profunda.
Middle sacral	with	Lateral sacral.
Ilio-lumbar and superior gluteal	with	Circumflex iliac.

THE PELVIS

The male pelvis will be considered first, then the female pelvis, and finally a section on hernia.

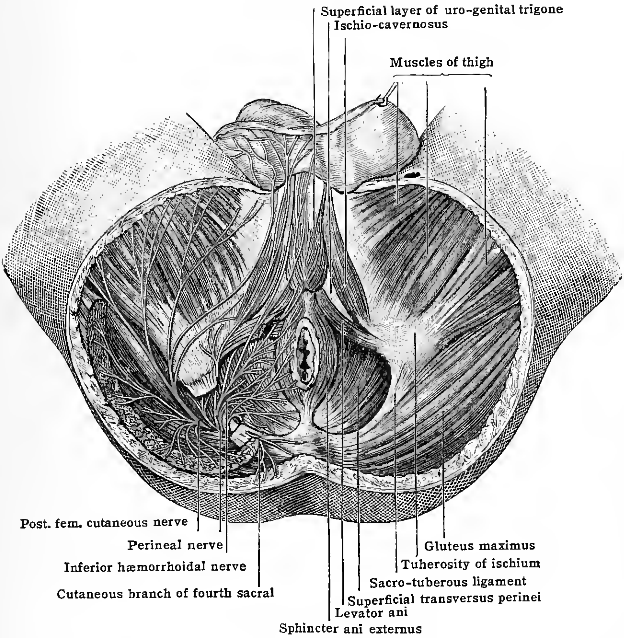
The Male Pelvis

The topics under this heading will be considered in the following order: boundaries and subdivisions, scrotum and testis, ductus deferens and spermatic cord, penis and urethra, prostate, bladder, ischio-rectal fossa, rectum and anal canal.

Bony boundaries.—These are the same in either sex. Above and in front is the symphysis pubis, rounded off by the subpubic ligament; diverging downward and laterally from this point on either side are the rami of the pubes and ischia, ending at the tuberosities of the latter. In the middle line behind is the apex of the coccyx, and reaching from this to the tuberosities are the sacro-tuberous (great sacro-sciatic) ligaments, to be felt by deep pressure, with the lower border of the gluteus maximus overlapping them.

The depth of the perineum varies greatly—from 5 to 7.5 cm. (2 to 3 in.) in the posterior and lateral part to 2.5 cm. (1 in.) or less in front. In the middle line, extending longitudinally through the perineum, is the raphe, the guide to the urethra, and 'the line of safety' (on account of the small size of the vessels here) for operations on it.

Fig. 1113.—The Male Perineum. (Modified from Hirschfeld and Leveillé.)



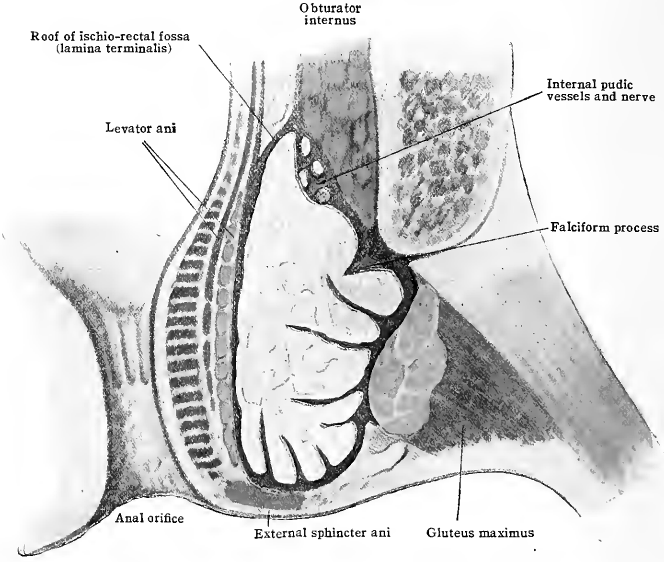
Subdivisions.—An imaginary line drawn transversely across the perineum from one tuber ischii to its fellow divides the lozenge-shaped space into **two triangles**—(1) An **anterior,** or **uro-genital**; and 2) a **posterior,** or **rectal.** The pelvic floor includes an upper or pelvic diaphragm (formed by the levator ani and coccygeus on each side) and a lower incomplete uro-genital diaphragm (or trigone).

The **pelvic diaphragm** (figs. 1113, 1114, 1115; see also figs. 397, 399, 400) is made up of the levator ani coccygeus muscles. It is somewhat funnel-shaped. When viewed from above or below (fig. 395), its fibres are seen to form horseshoe-like loops, arising on either side anteriorly, and passing posteriorly backward around the uro-genital apertures to be inserted chiefly in the mid-line posteriorly. The pelvic diaphragm serves primarily for the support of the abdominal viscera. For a detailed description of these muscles, as well as those of the uro-genital diaphragm, see section on the Muscular System.

The **uro-genital diaphragm** (or trigone) (fig. 400), the lower diaphragm of the pelvic floor, is both morphologically and functionally different from the upper. The uro-genital diaphragm is a sphincter muscular layer, derived (with the sphincter ani externus) from the primitive *sphincter cloacæ*. The uro-genital diaphragm is composed of superior and inferior fascial layers, enclosing the membranous urethra, the sphincter urethræ membranaceæ and the transversus perinei profundus. Superficial to the uro-genital diaphragm is the superficial perineal interspace (fig. 400). This is covered by the superficial perineal (Colles') fascia, and includes the crura and bulb of the corpora cavernosa, with associated muscles, vessels and nerves.

The space in the pelvic floor on each side below the pelvic diaphragm is the **ischio-rectal fossa** (figs. 399, 400, 1114). In the posterior or rectal triangle, where the urogenital diaphragm is absent, the ischio-rectal fossæ form large wedge-shaped spaces. The *lower* wall or base is formed chiefly by the corresponding skin and superficial fascia, and partly by the external sphincter ani; the *medial* wall by the

Fig. 1114.—Coronal Section of the Ischio-rectal Fossa. (G. Elliot Smith.)



muscles (levator ani and coccygeus) and inferior fascia of the pelvic diaphragm; the *lateral* wall by the obturator internus muscle, with the corresponding obturator fascia (with Alcock's canal, including the pudic vessels and nerves). The *apex* of the fossa is above, where medial and lateral walls meet. The narrow fibrous roof strip joining the medial and lateral walls just above the level of the internal pudic vessels and nerves has been called the *lamina terminalis* (Elliot Smith, fig. 1114). Posteriorly the fossa is bounded by the gluteus maximus and lig. sacro-tuberosum. Anteriorly on each side the ischio-rectal fossæ extend as narrow spaces between the pelvic diaphragm above, the uro-genital diaphragm below, and the pelvic wall laterally (figs. 400, 401, 402).

Contents.—The ischio-rectal fossa is filled with loose adipose tissue continuous with the subcutaneous fat of the buttock. It is traversed by the inferior hæmorrhoidal branches of the internal pudic artery, with the associated veins and nerves, passing to the external anal sphincter, the skin and the adjacent mucosa. The superficial vessels and nerves, as they run forward to pierce the superficial perineal fascia, lie in this space, as well as the inferior clunial (perforating cutaneous) branches and branches of the fourth sacral nerve. The inferior hæmorrhoidal veins traverse the fossa obliquely from the lateral wall downward and medially. They are usually somewhat dilated near the anal orifice, and when morbidly enlarged constitute the condition known as hæmorrhoids ("piles"). The inner opening of an anal fistula caused by the bursting of an ischio-rectal abscess into the gut is usually within 2 cm. of the anal margin, between the internal and external sphincters.

The **central point of the perineum** is in the adult nearly an inch (2.5 cm.) in front of the anus, or midway between the centre of the anus and root of the scrotum. Here the following structures meet, viz., the levatores ani, the two transverse perineal muscles, the bulbo-cavernosus, and the sphincter ani.

The comparative weakness of the attachment of the sphincter ani in front, i. e., not into a bony point, is important in the division of it, as in operation for fistula. The sphincter should never be cut through anteriorly, especially in women, where its attachment here, blending with the sphincter vaginæ, is a very weak one. This point also corresponds to the centre of the lower margin or base of the uro-genital diaphragm (triangular ligament). Its development varies much in different bodies. A little in front of this point is the bulb, with the corpus spongiosum passing forward from it. This would also be the level of the artery of the bulb, so that in lithotomy the incisiou should always begin below this point. A knife introduced at the central point, and carried backward and very slightly upward, should enter the membranous urethra just in front of the prostate, e. g., in median lithotomy and Cock's external urethrotomy. If pushed more deeply, it would enter the neck of the bladder.

In median lithotomy, an incision 3.7 cm. ($1\frac{1}{2}$ in.) long is made through the central tendinous point and raphe, so as to hit the membranous urethra. The following structures are divided:— Skin and fasciæ; some of the most anterior fibres of the external sphincter ani; raphe and central tendinous point; minute branches of transverse perineal vessels and nerves; base of uro-genital diaphragm in centre; membranous urethra and constrictor urethræ.

The attachments and arrangements of the **superficial fascia** (fig. 1115) must be traced and remembered. If the two layers of which it consists, the superficial alone extends over both urethral and rectal triangles alike, and is continuous with the similar structures in adjacent regions, the only difference being that, if traced foward into the scrotum and penis, it loses its fat, and contains dartos fibres. The deeper layer, found only over the urethral triangle, is called the fascia of Colles (fig. 1115). Attached at the sides to the rami of the pubes, behind to the base of the uro-genital trigone or diaphragm, and open in front, it forms the superficial wall of a somewhat triangular pouch, limited behind by the uro-genital trigone, and containing the superficial vessels, nerves, and muscles, the bulb, adjacent part of the urethra, and crura of the penis. Owing to this space being closed behind and open in front, and to its containing the above structures, fluids extravasated within this space will obviously tend to make their way forward into the scrotum, penis, and lower part of the abdominal wall.

The **uro-genital triangle** is subdivided into two planes by the inferior fascia of the uro-genital diaphragm and fascia of Colles. The structures *in the superficial plane,* between the uro-genital diaphragm and the fascia of Colles, have been given above. Those in the deeper, i. e., **between the two layers of fascia of the diaphragm,** are—(1) The membranous urethra; (2) deep transverse perineal muscle and sphincter of the membranous urethra; (3) the bulbo-urethral (Cowper's) glands; (4) and (5) part of the pudic artery and nerve, and branches.

The scrotum.—The skin of the scrotum is thin and delicate so that when distended, as by a hydrocele in the tunica vaginalis, it is remarkably translucent. Attached to its deep aspect is a layer of involuntary muscle, the dartos. When the dartos is contracted, as under the influence of cold, the scrotal skin becomes rugose.

To this tendency to wrinkling, with consequent irritation from retained dirt, and the presence of many sweat glands the frequency of epithelioma in this part is due. The dartos is apt to cause inversion of the skin in wounds of the scrotum, but this difficulty in suturing may be counteracted by the application of a hot sponge, which relaxes the muscle.

The superficial fascia of the scrotum is continuous with the fascia of Colles and the superficial fascia of the penis. Hence extravasation of urine under the fascia of Colles's balloons the scrotum and penis. The laxity of the areolar tissue under the dartos accounts for the great swelling that occurs in œdema of this part.

The lymphatics of the scrotum, important by reason of the extension of scrotal cancer, drain into the superficial inguinal nodes. Those from the anterior aspect nearest the median raphé run to the supero-lateral glands of this group, within a few cm. of the anterior superior spine.*

* Morley: Lancet, 1911 (ii), p. 1545.

The numerous large sebaceous glands that are found in the skin of the scrotum may give rise to cysts or adenomata. The deeper layers of the scrotum are derived from the abdominal wall, being brought down by the processus vaginalis in the descent of the testis.

Testis and epididymis.—The left testis, the first to descend, lies somewhat lower in the scrotum, and this fact is one reason of the frequency with which a

FIG. 1115.—THE ARTERIES OF THE PERINEUM.

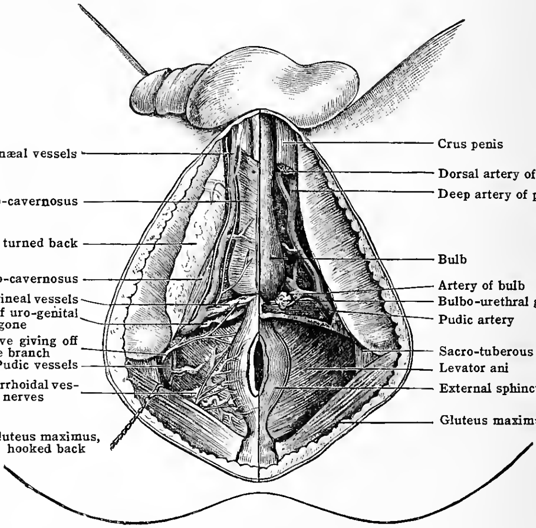


FIG. 1116.—SAGITTAL SECTION OF MALE PELVIS (×1/3). (Braune.)

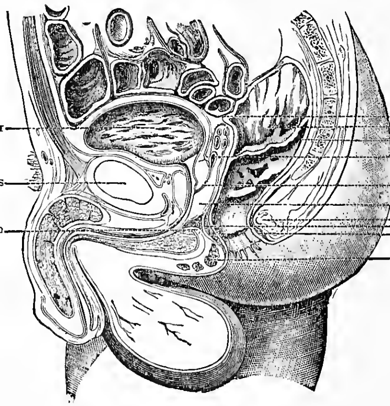


varicose condition of the spermatic veins occurs on the left side. On *palpation* the smooth firm body of the testis, pressure on which causes the characteristic "testicular sensation" can be felt to lie in front of and rather medially to the **epididymis.** The three parts of the latter, the *caput* above, the *body*, and the *cauda epididymidis* below, can also be distinguished. Running upward from the back of the epididymis to the subcutaneous inguinal ring the **spermatic cord** can be felt. The bulk of the cord is made up of its coverings, of which the cremaster muscle is the most considerable, and of the pampiniform plexus of veins. On rolling the cord between the finger and thumb the **ductus deferens** can be felt like a piece of whipcord in the posterior part.

The *ductus* (*vas*) *deferens* is thickened and nodular in tuberculous epididymitis. In varicocele the dilated and elongated veins of the pampiniform plexus feel on palpation like a bag of worms in the scrotum. It is important that the student, before studying diseased conditions, should make himself familiar with the feel of the normal parts as mentioned above and be able to identify them.

Underneath the visceral layer of the tunica vaginalis, the body of the testis is covered by a dense fibrous layer, the *tunica albuginea*, which accounts for the small extent of swelling in orchitis as compared with epididymitis. The *lymphatics* of the testis run up in the spermatic cord through the inguinal canal, and accompanying the spermatic vessels end in the lumbar lymph nodes, below the level of the renal arteries. These nodes may be reached and removed along with the vessels by making an incision in the loin above the inguinal (Poupart's) ligament, and stripping the peritoneum off the posterior abdominal wall.

On the right side of the perineum (left side of this figure) Colles's fascia has been turned back to show the superficial vessels. On the left side the superficial vessels have been cut away with the anterior layer of the uro-genital trigone to show the deep vessels.

The **epididymis** is the convoluted first part of the duct of the testis, about 6 m. (20 feet) in length. Its three portions are in differing connection with the testis. Thus the *cauda* is held in place by connective tissue, the *body* by the same medium; the *caput* by the vasa efferentia. Thus, when tubercular disease begins here, the testis itself is more likely to be early involved.

Ductus deferens.—The two extremities and the course of this involve several practical points. About 45 cm. (18 in.) long, it begins, convoluted at first and with a distinct bend upward, in the cauda epididymidis. It thence passes almost vertically upward at the back of the testis and cord to the tubercle of the pubes. Entering the canal, it lies on the grooved upper aspect of the inguinal (Poupart's) ligament, and then under the arching fibres of the internal oblique and transversus, upon the transversalis fascia. Its position, characteristic feel, and yellowish aspect are well-known guides in operations for varicocele and hernia, while it is always to be isolated and palpated when tubercular disease below is suspected. Leaving the canal by the abdominal inguinal ring, it hooks round the inferior epigastric artery and then descends into the pelvis over the external iliac vessels. Continuing its course downward and backward over the side of the pelvis, it arches backward over the side of the bladder, superficial to the obliterated hypogastric artery, and then deep to the ureter. The two ducts now help to form the lateral boundaries of the external trigone, between the base of the bladder and the rectum. They here become dilated and sacculated and then contract again to empty into the ejaculatory ducts.

The **vesiculæ seminales** are diverticula growing out from the lower end of the deferential ducts at an acute angle, one on each side. They lie below and lateral to the deferential ducts and are related in front to the base of the bladder and posterior surface of the prostate, behind to the rectum, and above to the recto-vesical pouch of peritoneum, which also descends to cover the upper part of their posterior aspect. The normal vesiculæ seminales can scarcely be distinguished from the base of the bladder on rectal palpation, but when diseased, as in tuberculous or gonorrhœal vesiculitis, are enlarged and indurated and can be detected readily.

The **ejaculatory ducts**, formed by the union of the vesicular and deferential duct of each side, are 2–2.5 cm. in length. The first few millimeters of their course is extra-prostatic, and then entering the posterior surface of the prostate they run side by side downward and forward through the gland, close to the middle line, to open into the urethra on the colliculus seminalis at either side of the opening of the prostatic sinus. It is by these little ducts that infection travels from the urethra to the vesiculæ and epididymis in gonorrhœa.

Descent of the testis.—The testis is developed between the tenth and twelfth thoracic segments of the embryo, and subsequently moves downward. By the third month of intra-uterine life it descends into the iliac fossa; from the fourth to the seventh month it lies at the abdominal inguinal ring; during the seventh month it passes obliquely through the abdominal wall by the inguinal canal; by the eighth month it lies at the subcutaneous inguinal ring, and it reaches the fundus of the scrotum about the time of birth. The left testis is slightly earlier than the right in all these stages. The descent referred to is due in part to the common descent of organs, associated with the descent of the diaphragm, but mainly to the **gubernaculum.** This is a mass of fibro-muscular tissue that forms under the *inguinal fold* (or *plica gubernatrix*) of peritoneum below the testis as it lies in the iliac fossa, and in the mesorchium. It grows down obliquely through the abdominal wall from a point lateral to the inferior epigastric artery, and tunnels out a passage for the testis. As it travels down into the scrotum it carries in front of it three layers of investing fascia derived from the abdominal wall, viz., external spermatic fascia from the external oblique, cremasteric from internal oblique and transversus muscles, and infundibuliform fascia from the transversalis fascia. The gubernaculum is attached above to the peritoneum and the posterior aspect of the testis, and by its subsequent contraction it draws down into the scrotum first a diverticulum of peritoneum, the **processus vaginalis**, and secondly the testis, which projects into the processus from behind just as it did into the cœlom.

Shortly after birth, obliteration of the processus vaginalis should occur, commencing at the deep abdominal ring and immediately above the testis. The part of the processus between these two points disappears completely. The lowest part, surrounding the testis, persists as the tunica vaginalis. Failure of obliteration, if complete, leaves a *congenital hernial sac;* if only the upper part perists, and does not communicate with the tunica vaginalis, it is called a *funicular* sac. Cysts originating in the processus vaginalis between the upper and lower points of primary occlusion are known as *encysted hydrocele of the cord.*

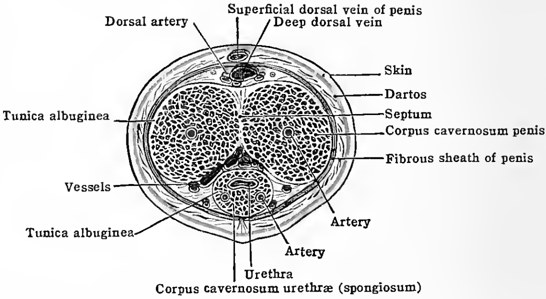
Undescended testis.—It occasionally happens that descent of the testis fails on one or both sides, and in these cases the organ may remain, (1) in the iliac fossa, (2) in the inguinal canal, or (3) at the subcutaneous ring. Deprived of the protection normally afforded against injury by the scrotum and tunica vaginalis, the misplaced testis is subject to trauma, shows a tendency to torsion of its pedicle owing to its long mesorchium, and sometimes becomes the seat of malignant disease. A funicular hernial sac is generally present. Such testes are atrophic and functionally deficient, and it is probably owing to their small size at an early stage that the gubernaculum fails to gain a hold on them. It has been shown by Bevan* that in undescended testis the ductus deferens is usually long enough to allow the organ to be placed in the bottom of the scrotum by the surgeon without tension provided that the spermatic artery and pampiniform plexus of veins are divided. The blood-supply of the organ is then entirely derived from the deferential artery, a branch of the superior vesical. In rare cases the testis descends in a wrong direction (ectopia testis) and comes to lie in the perineum, over Scarpa's triangle, or on the pubes.

Penis.—The subcutaneous tissue of the penis, as on the scrotum, is devoid of fat and the delicate skin is very mobile and distensible, hence the ballooning of these parts in extravasation of urine or œdema. The fascia penis is continuous with Colles's fascia.

In radical amputation of the penis for malignant disease the whole organ, including the crura, is removed through an incision that splits the scrotum, and the stump of the corpus spongiosum (corpus cavernosum urethræ) is brought out into the perineum behind the scrotum.

The preputial orifice varies greatly in size. Normally large enough to allow easy retrac-

Fig. 1117.—Cross-section of Penis.



tion of the prepuce from off the glans, it is frequently so small that retraction is impossible and it may even cause difficulty in micturition. The mobility of the skin over the penis must be borne in mind in the operation of circumcision, and care taken lest too much of the prepuce be removed, leaving insufficient skin to cover the penis. In this operation the vessels from which bleeding occurs lie, (1) on the dorsum, (2) in the frenum.

Congenital malformations of penis.—At an early stage of development the urethra opens on the inferior aspect of the penis behind the glans. After the ingrowth of epithelium that forms the glandular urethra, this primitive meatus should close. Occasionally, however, it persists, and the glandular urethra is represented by a groove on the under aspect of the glans. In these cases of *hypospadias* the glans is flexed on the penis and the prepuce is deficient below and has a peculiar "hooded" appearance. In *epispadias* the upper wall of the urethra and corresponding part of the corpora cavernosa are absent. This condition is usually present in cases of ectopia vesicæ.

The **male urethra** is about 20 cm. (8 in.) in length, consisting of the **cavernous** portion, 16 cm. ($6\frac{1}{2}$ in.), **membranous** 1 cm. ($\frac{2}{5}$ in.) and **prostatic** 3 cm. ($1\frac{1}{4}$ in.). The narrowest part is the external orifice, and next to it the membranous urethra. The prostatic urethra is the widest and most dilatable. The bulbous urethra, just in front of the uro-genital diaphragm, is wider than the rest of the penile portion, but since it forms the most dependent spot in the fixed part of the urethra (from bladder to suspensory ligament of penis), it is specially prone to gonorrhœal stricture. Behind the bulb, the urethra narrows suddenly as it passes through the uro-genital diaphragm and contraction of the sphincters of

* Journ. Amer. Med. Assoc., vol. 41, 1903, p. 718.

the membranous urethra may here give additional difficulty in the passage of a catheter.

False passages most commonly occur through the floor of the bulb on account of this, difficulty in entering the membranous urethra. The point of a small catheter may also be caught in the following apertures: (1) The lacuna magna in the roof of the fossa navicularis of the glandular urethra; (2) other crypts or lacunæ in the penile part, mostly situated in the upper wall; (3) the prostatic sinus in the floor of the prostatic urethra about its centre. With the penis raised the urethra presents a simple curve under the symphysis with the proportions of an ordinary silver catheter.

It is in the region of the uro-genital diaphragm that the urethra is most liable to be damaged by a fall or blow, and the urine extravasated as a result will be beneath Colles's fascia. In rupture of the membranous urethra urine may find its way in front of the inferior fascia of the uro-genital diaphragm by coexisting injury to this, or through openings in the vessels, etc.; in a few such cases urine will make its way backward behind the fascia into the space of Retzius, ascending thence between the peritoneum and transversalis fascia. The attachment of the deep layer of superficial fascia to the base of the uro-genital diaphragm accounts for the fact that urine extravasated from a ruptured urethra or through an opening behind a stricture passes not backward into the anal triangle, but forward onto the scrotum and abdominal wall.

The **prostate** consists of a mass of racemose glandular tubules imbedded in a fibro-muscular stroma, that surrounds the first part of the urethra and lies below the neck of the bladder. Its **base** is intimately connected with the bladder by the continuation of vesical and urethral mucous membrane and by the insertion of the outer longitudinal muscular coat of the bladder into the gland. The inner circular muscle fibres of the bladder become specialised round the internal urethral orifice to form the *internal sphincter.*

Adenomatous enlargements of the gland usually grow upward through this sphincter which is thus dilated and pushed aside, so that the glandular growth is covered only by vesical mucous membrane.

The **apex** of the prostate lies at the level of the lower border of the pubic symphysis and 1.5 cm. behind it. It is firmly fixed to the superior fascia of the uro-genital diaphragm (deep layer of the uro-genital trigone) and here the urethra leaves it to become the membranous part. The **anterior surface** directed vertically lies 2 cm. behind the lower part of the pubic symphysis in relation to the prostatic plexus of veins; and from it the dense pubo-prostatic ligaments run forward on either side to the pubes. The **posterior surface** is in contact with the rectum, through the anterior wall of which it may be palpated 4 cm. ($1\frac{1}{2}$ in.) above the anal margin. It is separated from the rectum by the two layers of the recto-vesical septum (Elliot Smith).* The **lateral surfaces** are supported by the anterior fibres of the levator ani, from which, however, they are separated on each side by a dense mass of fibrous tissue in which the pudendal (prostatic) plexus of veins is imbedded.

The *prostatic urethra* traverses the gland nearer the anterior than the posterior surface, with a slight forward concavity. Its floor is placed posteriorly and presents an eminence, the *colliculus seminalis,* about the centre of which is the orifice of the prostatic sinus, on either side of which open the common ejaculatory ducts. The prostate is indefinitely divided into two lateral lobes. The fissure uniting them across the middle line in front of the urethra (the anterior commissure) is fibro-muscular and contains no glandular tissue. Behind the urethra the lateral lobes are continuous and the portion of gland lying between bladder, ejaculatory ducts and urethra has been erroneously termed the "middle lobe." Though not a separate lobe anatomically, adenomatous hypertrophy of this part is common, when it projects up into the bladder, and prevents the proper emptying of that organ.

Capsule and sheath of the prostate.—In senile enlargement of the prostate removal may be effected by the *suprapubic* or by the *perineal* route. In the former, the bladder is opened above the pubes, the mucous membrane lying over the gland as it projects into the bladder is scratched through behind, and with the finger the whole adenomatous mass is enucleated. This process usually involves tearing out the whole of the prostatic urethra, and the ejaculatory ducts. The parts left behind consist of (1) the "**capsule**" which is simply the outer part of the gland proper stretched over the adenomatous mass, and consists of fibro-muscular tissue with a few flattened glandular tubules (C. Wallace).† Outside this (2) the fibrous "sheath" is derived from the visceral layer of pelvic fascia, in which is imbedded, on the anterior and lateral aspects of the gland, the prostatic plexus. Since these veins are not torn there is com-

* Studies in Anatomy of the Pelvis. Journ. Anat. and Physiol., vol. 42, 1908.

† C. Wallace. Prostatic Enlargement, 1907.

paratively little hæmorrhage. In the *perineal* operation the posterior surface of the gland is exposed by cutting through the perineum between the bulb and external sphincter ani, and dividing the attachment of the recto-urethral muscle to the uro-genital diaphragm and its inferior fascia. This exposes the back of the recto-vesical septum (aponeurosis of Denonvilliers) which is split at its base, opening up the recto-prostatic space of Proust. By a longitudinal incision into the prostate on each side the adenomatous lateral lobes may be enucleated separately, and it is claimed without injury to the urethra or ejaculatory ducts (Hugh Young).*

The **bladder** lies above the pubic symphysis at birth and so is mainly an abdominal organ. The *anterior surface*, in contact with the abdominal wall, has no peritoneal covering, but posteriorly the peritoneal reflection descends to cover the posterior surface of the prostate, which is relatively lower than in the adult.

The adult bladder when empty forms a pyriform contracted organ behind the symphysis, and bounding the retro-pubic space of Retzius posteriorly. Into this space urine is extravasated in extra-peritoneal rupture of the bladder, and may mount up behind the abdominal wall in the extra-peritoneal tissue. The space is closed below by the pubo-prostatic ligaments and prostatic plexus of veins. In distention, the *neck* of the bladder and prostate being relatively fixed and immovable, the free *apex* rises up into the abdomen. As it does so it raises the peritoneum off the abdominal wall, so that in moderate distention 5 cm. (2 in.) of abdominal wall above the pubes are free of peritoneum, and the bladder may be tapped here safely. The *upper surface* and a little of the posterior are covered by peritoneum, which is also related to the upper halves of the vesiculæ seminales. Below the recto-vesical pouch the *base* of the bladder presents a small *triangular area* in contact with rectum, bounded by the peritoneal *cul-de-sac* above, the converging deferential ducts on each side and the prostate below. Through this triangle which is rather expanded in distention of the bladder, puncture *per rectum* was formerly practised. The *infero-lateral surfaces* are slung up by the levator ani as by a hammock. The *interior* of the bladder can be examined by the **cystoscope** in the living patient. The mucous membrane is loose and rugose in contraction, except over the trigone at the base, the angles of which are formed by the ureteric orifices and the internal meatus. The mucosa here is firmly adherent to the muscular coat and smooth. In hypertrophy of the bladder-muscle from obstruction, a fasciculated appearance of the mucosa is seen and possibly diverticula between the bands of muscle.

Rectum and anal canal.—The rectum proper extends from the end of the pelvic colon, opposite the third sacral vertebra, to the upper end of the narrow anal canal, which runs downward and backward almost at right angles to the rectum and is 3–4 cm. in length. The commencement of the rectum lies 13–14 cm. (5–5½ in.) above the anus in the adult. This point is marked internally by an infolding of the mucosa on the right and anterior wall and to some extent of the circular muscle fibres, due to the angle at which the free pelvic colon turns into the fixed rectum. This shelf of mucous membrane is known as the **upper transverse fold** (first valve of Houston).

Under normal conditions the rectum does not form a reservoir for fæcal material, which is stored in the lower end of the pelvic colon, above the upper transverse fold, leaving the rectum empty except in defæcation. The rectum proper is subdivided into two compartments by the **inferior transverse fold** on the anterior wall (third or great valve of Houston), situated 8–9 cm. (3–3½ in.) above the anus at the level of the anterior cul-de-sac of the peritoneum, and resulting from the adaptation of the rectum to the hollow of the sacrum. This can usually be made out on digital examination. The other transverse folds are inconstant and only present on great distention.

The rectum and anal canal may be divided into three regions: (1) **peritoneal** from the third sacral vertebra to the lower transverse fold and anterior reflexion of peritoneum onto bladder or vagina; (2) **infraperitoneal** (rectal ampulla) below this and above the levator ani; (3) **anal canal,** below the level of the levator ani, constriction by which marks it off from the ampulla and converts it into an antero-posterior slit.

The **mucous membrane** of the rectum proper is redundant and mobile and of a bright pink colour as seen by the sigmoidoscope. It is dotted over by **rectal pits,** visible to the naked eye, containing lymphoid follicles, and by the smaller and more numerous **Lieberkhün's glands.** In the peritoneal chamber the mucosa is transversely plicated. In the rectal ampulla it presents longitudinal folds in which lie branches of the superior hæmorrhoidal vessels. These longitudinal folds, known as the **rectal columns,** converge into the anal canal, and end at the level of the **anal valves** half way down the canal, each uniting two adjacent valves. The anal valves probably represent the original cloacal membrane, dividing the proctodæum (formed from the epiblast) from the hypoblastic hindgut, and persistence of this membrane gives one form of imperforate anus (Wood Jones†). The tearing down of a valve by hard fæces may be a cause of anal fissure, etc. (Ball). The mucous membrane of the anal canal is more firmly adherent

* Studies on Hypertrophy and Cancer of the Prostate. J. H. H. Reports, vol. 14, 1906.
† Brit. Med. Journal, Dec. 14, 1904.

to the underlying muscular coat than that of the rectum, hence in prolapse the mucosa of the rectal ampulla is the first to be extruded.

Peritoneal relations.—The peritoneal chamber of the rectum has no covering of peritoneum behind, and the peritoneum, at first covering its first aspect and sides, leaves the sides obliquely and finally is reflected onto the base of the bladder (or the vaginal fornix in the female), at the level of the inferior rectal fold, 8 cm. from the anus.

Blood-supply.—(1) The **superior hæmorrhoidal artery,** a continuation of the inferior mesenteric, reaches the rectum behind, via the pelvic meso-colon and bifurcates at once. The two branches run round on either side below the peritoneal reflection; giving off secondary branches that pierce the muscular coat about the level of the inferior transverse fold, or anterior peritoneal reflection. Joining the submucous layer, these arteries run down in the rectal columns to the anal canal, where they anastomose with (2) the **middle hæmorrhoidal arteries,** branches of the hypogastric (internal iliac) and (3) the **inferior hæmorrhoidal** branches of the internal pudendal. The veins correspond. Their free anastomosis in the **hæmorrhoidal plexus** under the rectal columns, the union afforded here between the portal and systemic veins, the absence of valves in the superior hæmorrhoidal veins, and the constriction they are subject to in passing through the muscular coat, are some of the anatomical causes of the frequency of hæmorrhoids.

The branches of the superior hæmorrhoidal artery to the rectum anastomose but little with one another, as compared with the sigmoid arteries to the pelvic colon. The main trunk of the superior hæmorrhoidal usually receives a large anastomotic branch from the lowest sigmoid artery 1–2 cm. below the sacral promontory, upon which the upper part of the rectum is dependent for its blood-supply after ligature of the superior hæmorrhoidal. Hence in high excision of the rectum it is important to place the ligature on the superior hæmorrhoidal above the sacral promontory if sloughing of the gut is to be avoided.*

For lymphatics of the rectum see p. 735.

Supports of the rectum.—The anal canal is fixed by its attachment to the levator ani and perineal body. After division of the perineal body and recto-urethral muscle in front, the rectum is readily separable from the back of the prostate and recto-vesical septum. When the levator ani has been divided on each side and the peritoneum opened, as in the perineal operation for excision of the rectum, the gut cannot be pulled down freely. The hand passed up behind it in the hollow of the sacrum meets on each side with a dense fibrous layer running from the sacrum opposite the third foramen onto the side of the rectum. This is the *rectal stalk* (Elliot Smith) and consists of dense fibrous tissue round the nervi erigentes from second, third and fourth sacral foramina and the middle hæmorrhoidal vessels. It lies about 2.5 cm. above the levator ani, and after division of it the bowel is easily freed, so that the whole of the rectum and part of the pelvic colon may be drawn out at the perineum without tension.

Rectal examination.—The following points can be made out by the finger introduced into rectum:—(1) The thickened, roll-like feel of a contracted external sphincter; (2) the narrower, more expanded, internal sphincter extending upward for 2.5 cm. (1 in.) from this; (3) the rectal insertion of the levatores ani, which here narrows somewhat the lumen of the gut; (4) above the anal canal, with its contrasting capaciousness, is the more or less dilated rectum proper; (5) the condition of the ischiorectal fossæ on either side; (6) the membranous urethra in front, especially if a staff has been introduced; the instrument now occupies the middle line, and has the normal amount of tissue between it and the finger, thus differing from one in a false passage (in a child an instrument is especially distinct); (7) just beyond the sphincters, or 3.7 cm. ($1\frac{1}{2}$ in.) within the anus, lies the prostate; (8) converging toward the base of the prostate, and formiug the sides of the triangular space, are the vesiculæ seminales and ejaculatory ducts. These can rarely be felt unless diseased and enlarged; any enlargement of the sacculated ends of the deferential ducts is much more perceptible; (9) it is within this triangular space that the elasticity of a distended bladder can be felt. (10) Usually the lowest of the transverse folds (folds of Houston), semilunar in form and about 1.2 cm. ($\frac{1}{2}$ in.) in width, can be made out (fig. 1116). (11) Behind, the coccyx and its degree of pliability and the lower part of the sacrum. It may also be possible to feel enlarged sacral nodes and a growth from the other pelvic bones.

The above examination refers chiefly to the male. It remains to refer to **rectal examination in the female.** Anteriorly, the soft perinæal body and recto-vaginal septum will be met with, and, through the latter, the cervix and os uteri, and, higher up, the lower part of the cervix uteri. More laterally the ovaries may be felt, but the uterine or Fallopian tubes, unless enlarged and thickened, are not to be made out. The student should be familiar with the feel of a healthy recto-uterine or recto-vesical pouch, according to the sex, and the coils of intestine which it may contain, so as to be able to contrast this with any collection of inflammatory or other fluid or mischief descending from the upper pelvis, e. g., from the vermiform appendix. Posteriorly, certain structures are met with in either sex. After a very short interval (sphincter and ano-coccygeal body) the finger reaches the tip of the coccyx and explores the hollow of the sacrum. On each side are the ischial tuberosity and wall of the true pelvis. The finger hooked lateralward and upward, comes on the border of the falciform process of the sacro-tuberous (great sacro-sciatic) ligament, passing between the above-mentioned bones.

FEMALE GENITAL ORGANS

The external organs will be considered first, followed by the internal. Under the external organs are included, for convenience sake, the labia majora and minora at the sides; and, in the middle line, from above downward—(1) The glans clitoridis with its prepuce; (2) the vestibule; (3) the urethral orifice; (4) the

* H. Hartmann. Annals of Surgery, Dec., 1909.

vaginal orifice with the hymen or its remains; (5) the fossa navicularis; (6) the fourchette; (7) the skin over the base of the perineal body.

These parts have been described elsewhere, and only those points which are of importance in a clinical examination will be alluded to here.

The **labia majora** are two thick folds of skin, covered with hair on their outer surface, especially above, where they unite (*anterior commissure*) in the mons Veneris. They contain fat, vessels, and dartos, but become rapidly thinner below, where they are continuous at the front of the perineum (their *posterior commissure*).

When the above folds are drawn aside, the **labia minora,** or **nymphæ,** appear, not projecting, in a healthy adult, beyond the labia majora. They are small folds of skin, which meet above in the prepuce of the clitoris, and below blend with the labia majora about their centre. Sometimes, especially in nulliparæ, they unite posteriorly to form a slight fold, the fourchette.

The glans clitoridis, covered by its prepuce, occupies the middle line above.

Below it comes the **vestibule,** a triangular smooth surface of mucous membrane, bounded above by the clitoris, below by the upper margin of the vaginal orifice, and laterally by the labia minora. In the middle line of the vestibule and toward its lower part, about 12 mm. ($\frac{1}{2}$ in.) below the glans clitoridis, and 25 mm. (1 in.) above the fourchette, is the meatus or opening of the urethra (figs. 1034, 1037).

The **vaginal orifice** lies in the middle line between the base of the vestibule above, and the fossa navicularis below. Its orifice is partially closed in the virgin by a fold of mucous membrane, the **hymen** (fig. 1037). This is usually crescentic in shape attached below to the posterior margin of the vaginal orifice, and with a free edge towards the base of the vestibule. In some cases it is diaphragmatic i. e. attached all around, but perforated in the centre (fig. 1037).

The schrivelled remains of the hymen probably constitute the **carunculæ hymenales.** On either side of the vaginal orifice, at it lower part, lie the racemose, muciparous, **vestibular glands** (glands of Bartholin), situated beneath the superficial perineal fascia and sphincter vaginæ. Their ducts run slightly upward and open, external to the attachment of the hymen, within the labia minora. In relation to the upper two-thirds of the vaginal orifice, placed between the urogenital diaphragm behind and the sphincter vaginæ in front, are the vascular **bulbs** of the vestibule, rupture of which produces pudendal hæmatocele.

Fourchette and fossa navicularis.—The fourchette, as stated above, is the posterior commissure of the labia minora. Normally the inner aspect of this is in contact with the lower surface of the hymen. When the fourchette is pulled down by the finger, a shallow depression is seen, the **fossa navicularis,** with the fourchette for its posterior, and the hymen for its anterior, boundary.

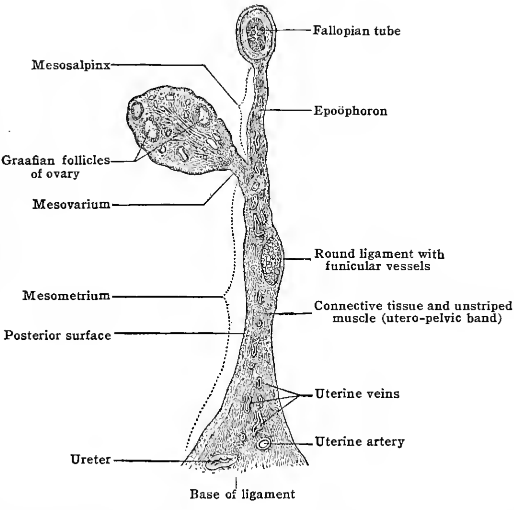
Internal organs.—The examinations through the vagina and anus will be considered first, followed by uterus and appendages, ovary and ureter.

Examination per vaginam.—The finger, introduced past the gluteal cleft, perineum, and fourchette, comes upon the elliptical orifice of the vagina, and notes how far it is patulous or narrow; the presence or otherwise of any spasm from the adjacent muscles; then, passing into the canal itself, the presence or absence of rugæ, a naturally moist or a dry condition are observed. In the *anterior wall* the cord-like urethra can be rolled between the finger and the symphysis; and further up than this, if a sound be passed, the posterior wall of the bladder. The anterior wall of the vagina is about 6.7 cm. ($2\frac{1}{2}$ in.) long. The *posterior wall,* 7.5 cm. (3 in.) long, forms the recto-vaginal septum, and through it any fæces present in the bowel are easily felt. The cervix uteri is next felt for in the *roof* of the vagina, projecting downward and backward in a line drawn from the umbilicus to the coccyx. Besides its direction, its size, shape, mobility, and consistence should be noted. The os uteri should form a dimple or fissure in the centre of the cervix. Of its two lips, the posterior is the thicker and more fleshy feeling of the two. The vaginal *culs-de-sac* or fornices are next explored. These should be soft and elastic, giving an impression to the finger similar to that when it is introduced into the angles of the mouth. Any resistance felt here may be due to scars, swellings connected with the uterus (displacements or myomata), effusions of blood or inflammatory material, and, in the case of the lateral *culs-de-sac,* a displaced or enlarged ovary, or dilatations of the Fallopian tubes. The posterior cul-de-sac is much deeper than the anterior, and, owing to the peritoneum descending upon the posterior wall of the vagina, when the finger is placed here it is only separated from the peritoneal sac by the vaginal wall and pelvic fascia. In examination of the pelvic organs the bimanual method, by which one hand on the hypogastric region, pushes them down and steadies them as well, is always to be employed to complete an examination.

The uterus and appendages.—The normal non-gravid uterus is usually anteflexed and anteverted so as to lie with its long axis approximately at right angles to that of the vagina. Its position varies considerably with the degree of distention of the bladder in front and of the rectum behind. The distance from external os to fundus, as estimated by the passage of a sound is in the adult virgin uterus 5.5 cm. of which 3 cm. belong to the cervix and 2.5 cm. to the body. In the empty multiparous uterus the total length of the cavity is 6 cm., 2.5 cm. comprising the neck and 3.5 cm. the body.

Peritoneal relations.—In front the peritoneum is reflected from the uterus to form the utero-vesical pouch at the level of the isthmus. Behind it covers not only the uterus but the posterior fornix of the vagina, before turning off onto the front of the rectum. Laterally the peritoneum leaves the uterus and passes on to the lateral pelvic wall as a large twofold partition fig. 1118), the broad ligament.

FIG. 1118.—SAGITTAL SECTION OF THE BROAD LIGAMENT.



The **broad ligament**, bearing in its upper border the uterine tube, in front the round ligament and behind the ovary, consists of (1) an upper thin part, the mesosalpinx lying above the attachment of the mesovarium, and containing the ovarian vessels and the epoöphoron, and below this (2) the thicker mesometrium, between the layers of which is a dense mass of fibrous tissue surrounding the uterine artery.

The anterior aspect of the cervix below the utero-vesical pouch of peritoneum, is readily separable from the bladder with which it lies in contact, and the peritoneum may be raised off the uterus with ease in the lower part of its attachment both front and back. Over the upper part of the body and fundus, however, the peritoneal covering is firmly adherent, and cannot be dissected off.

The **ovary,** attached by its hilum to the mesovarium, lies in a fossa at the back of the lateral wall of the pelvis just between the diverging external iliac and hypogastric vessels. To feel it the finger should be pushed well up in the side of the vagina toward the lateral wall of the pelvis. On the abdominal surface its position corresponds to the middle of a line drawn from the anterior superior iliac spine of that side to the opposite pubic tubercle (Rawlings).

The *lymphatics* of the ovary follow the ovarian veins (see p. 745).

Supports of the uterus.—The great mobility of the body of the uterus has been referred to above. The organ derives its support almost entirely from the attachments of the cervix and vaginal fornices. These rest on the pelvic floor, formed by the levator ani and perineal body which support them the more efficiently since the long axis of the vagina is at right angles to that of the uterus. Above the pelvic diaphragm the cervix is held up to the pelvic walls by strong specialised bands of fibro-muscular tissue running in both antero-posterior and transverse directions. The chief of these, lying in the base of the broad ligaments is a fibrous sheath surrounding the uterine artery as it descends medially from the hypogastric. In the antero-posterior direction the utero-vesical ligaments hold up the cervix to the pubes in front and the sacro-uterine ligaments bind it to the anterior aspect of the sacrum behiind. While firmly supporting the uterus these bands are elastic, and so do not fix it rigidly, but allow of the cervix being drawn downward by traction with vulsellum forceps.

For *lymphatics* of uterus and vagina see p. 745.

The ureter.—The pelvic portion of this duct is of special importance in operations on the uterus and upper vagina. It crosses the brim of the pelvis on either side at the bifurcation of the common iliac artery, or just in front of it, and descends on the side wall in front of the hypogastric artery, crossing the obliterated umbilical 'and obturator arteries. Curving forward and medially it passes under the base of the broad ligament, where the uterine artery crosses above it, and so gains the lateral angle of the bladder by passing across in relation to the lateral fornix of the vagina. In the base of the broad ligament the ureter lies about 2 cm. ($\frac{4}{5}$ in.) from the side of the cervix, and this relation must be borne in mind in excision of the uterus.

Pelvic floor.—The pelvic floor of the female corresponds in general to that of the male (see p. 1383). There are, however, important differences, due to the sexual organs. The *urogenital diaphragm* is relatively smaller in area, due to perforation by the vagina. The *pelvic diaphragm* is also correspondingly modified, and the pubo-coccygeus component is more strongly developed (see section on MUSCULATURE.) The *ischio-rectal fossa* is similar to that of the male (p. 1384).

HERNIA

Three varieties of hernia will be considered, inguinal, femoral, and umbilical

PARTS CONCERNED IN INGUINAL HERNIA

In inguinal hernia, as in femoral and umbilical, there is a weak spot in the abdominal wall—one weakened for the needful passage of the testicle from within to outside the abdomen (p. 1387). The parts immediately concerned are the two inguinal rings, subcutaneous (external) and abdominal (internal), and the canal. Now, it must be remembered at the outset that the rings and canal are only potential—they do not exist as rings or canal save when opened up by a hernia, or when so made by the scalpel. The canal is merely an oblique slit or flat-sided passage. The subcutaneous and abdominal rings are so intimately blended with the structures that pass through them, and so filled by them, that they are potential rings only.

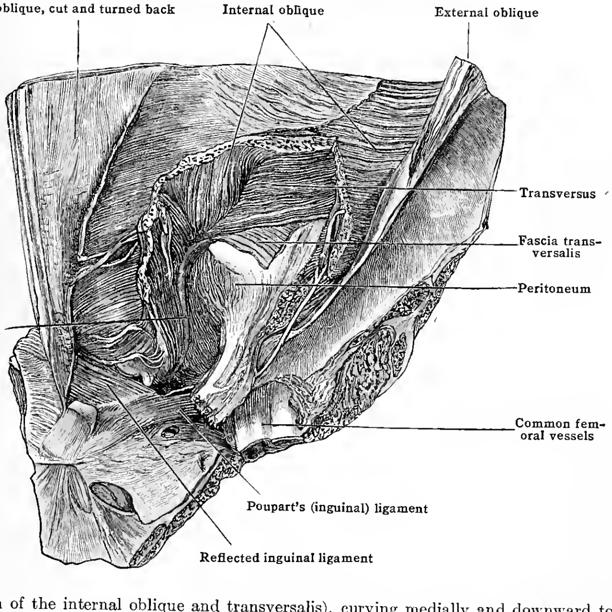
The subcutaneous inguinal (external abdominal) ring.—This is usually described as a ring: it is really only a separation or gap in the aponeurosis of the external oblique, by which in the male the testicle and cord, and in the female the round ligament by which the uterus is kept tilted a little foward, pass out from the abdomen. The size of this opening, the development and strength of its crura or pillars, the fascia closing the ring—all vary extremely. **Formation:** by divergence of two fasciculi of the external oblique aponeurosis. **Boundaries:** two crura—(1) Superior, the smaller, attached to the symphysis and blending with the suspensory ligament of the penis; (2) inferior, stronger, attached to the pubic tubercle and blending with the inguinal ligament, and so with the fascia lata. On this inferior, stronger crus rests the cord (and so the weight of the testicle) or round ligament. **Shape:** triangular or elliptical, with the base downward and medially toward the pubic crest.

Intercrural fibres (intercolumnar fascia) (external spermatic fascia).—This, derived from the lower part of the aponeurosis of the external oblique, ties the two crura together, and, being continued over the cord, prevents there being any ring here, unless made with a scalpel. This is the rule in the body: when any structure passes through an opening in a fibrous or muscular layer, it carries with it a coating of tissue from that layer; e. g., the inferior cava passing through its foramen in the diaphragm, and the membranous urethra through the uro-genital diaphragm.

Effect of position of the thigh on the ring.—As the lower crus is blended with Poupart's ligament, and as the fascia lata is connected with this, movements of the thigh will affect the ring much, making it tighter or looser. Thus extension and abduction of the thigh stretch the crura and close the ring. In flexion and adduction of the thigh the crura are relaxed; and this is the position in which reduction of a hernia is attempted. In flexion and abduction of the thigh, the ring is open; and this is the position in which a patient should sit, with thighs widely apart, to try on a truss, and cough or strain downward, as in rowing. If the hernia is now kept up, the truss is satisfactory.

Helping to protect this most important spot, and preventing its being more than a potential ring, are not only the two crura and the intercrural fibres, but also a structure which has been called a third or posterior pillar, namely, the **reflected inguinal ligament.** This has its base above at the lower part of the linea alba, where it joins its fellow and the aponeurosis of the external oblique, and its apex downward and laterally, where, having passed behind the medial crus it blends with the lacunar (Gimbernat's) ligament. Again, the **falx inguinalis** (the con-

FIG. 1119.—THE PARTS CONCERNED IN INGUINAL HERNIA.
(From a dissection in the Hunterian Museum.)



joined tendon of the internal oblique and transversalis), curving medially and downward to be attached to the ilio-pectineal line and spine, is a most powerful protection, behind, to what is otherwise a weak spot and a potential ring.

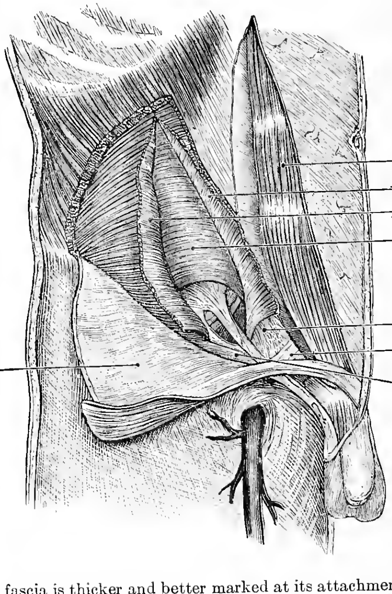
Inguinal canal.—This is not a canal in the usual sense, but a chink or flat-sided passage in the thickness of the abdominal wall. The descriptions of the canal usually given apply rather to the diseased than to the healthy state. It was a canal once, and for a time only, i. e., in the later months of fœtal life (p. 1387). It remains weak for a long time after, but only a vestige of it remains in the well-made adult.

Length.—In very early life there is no canal; one ring lies directly behind the other, so as to facilitate the easy passage of the testis. In the adult it measures about 37 mm. ($1\frac{1}{2}$ in.) in length, this lengthening being brought about by the growth and separation of the alæ of the pelvis. This increased obliquity gives additional safety. On the other hand, a large hernia has not only opened widely the canal and rings, but it has pulled them close together, and one behind the other thus not only rendering repair much more difficult, but also the path to the peritoneal sac shorter and more direct. **Direction.**—From the abdominal to the subcutaneous ring, downward, forward, and medially.

Boundaries.—For convenience sake, certain limits (largely artificial) have been named:—

(1) *Floor.*—This is best marked near the outlet, where the cord rests on the grooved upper margin of the inguinal (Poupart's) and the lacunar (Gimbernat's) ligament. The meeting of the transversalis fascia with this ligament forms the floor. (2) *Roof.*—The apposition of the muscles and the arched border of the internal oblique and transversus. (3) *Anterior wall.*—Skin, superficial fascia, external oblique for all the way. Internal oblique, i. e., that part arising from Poupart's ligament, for the lateral third or so. To a slight extent, the transversus and the cremaster. (4) *Posterior wall.*—For the whole extent, transversalis fascia, extraperitoneal tissue, and peritoneum. For the medial two-thirds, conjoined tendon of internal oblique and transversus, and the lateral edge of the reflected inguinal ligament, when developed.

FIG. 1120.—DISSECTION OF INGUINAL CANAL. (Wood.)



The transversalis fascia is thicker and better marked at its attachments below; these are—(*a*) laterally, to medial lip of iliac crest; (*b*) to the inguinal ligament between the anterior-superior spine and the femoral vessels, where it joins the fascia iliaca; (*c*) opposite the femoral vessels it also joins the fascia iliaca, and forms with it a funnel-shaped sheath; (*d*) medial to the femoral vessels the fascia transversalis is attached to the terminal (ilio-pectineal) line, behind the conjoined tendon, with which it blends. The *falx inguinalis* (*conjoined tendon*) needs special reference. It is formed by the lower fibres of the internal oblique and transversus (arciform fibres) arching downward over the cord to be inserted into the crest and spine and the terminal (ilio-pectineal) line. The fibres of the internal oblique become increasingly tendinous as they descend, and this, with the fact that below they give off the cremaster, may cause some difficulty in their identification when it is desired to unite them to the upper surface of Poupart's ligament in the operation of radical cure.

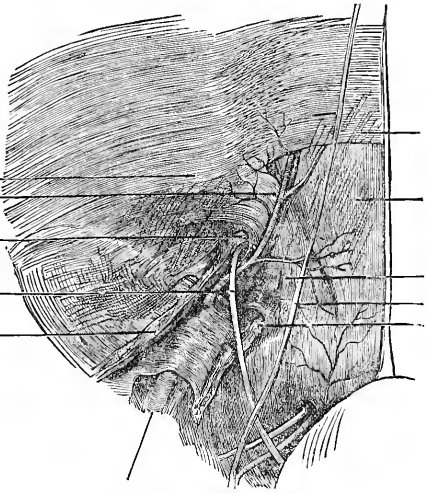
The abdominal inguinal (internal abdominal) ring.—It has already been said that the term 'ring' is here misapplied except in an artificial sense, as when an opening is made by a scalpel; or in abnormal conditions when a hernial sac is present. The abdominal ring is not a ring in the least, but merely a funnel-shaped expansion of the transversalis fascia, which the cord carries on with it as it escapes from the abdomen.

Site.—Midway between the anterior superior iliac spine and pubic tubercle. **Shape:** oval, with the long diameter vertical. **Boundaries:** centre of inguinal (Poupart's) ligament, about 12 mm. ($\frac{1}{2}$ in.) below. Medially, the inferior epigastric artery (fig. 1121); the position of this vessel, by its pulsation, is an important guide to the insertion of the highest sutures between the arciform fibres and the inguinal ligament. Owing to the artery lying to the medial side, the incision, in cutting to relieve the deep constriction of an inguinal hernia, should always be made directly upward, so as to avoid the above vessel. A large oblique hernia may so have altered the relations of the parts, including the artery, that it is difficult to decide whether the hernia is oblique or direct. The above incision will be safe, because, in either case, parallel to the vessel.

Coverings.—There are two chief forms of inguinal hernia:—

A. **The common form: lateral, or oblique.**—**Lateral,** because it appears (at the abdominal ring) lateral to the inferior epigastric artery. **Oblique,** because it traverses the whole of the inguinal canal, entering it at its inlet and leaving it at its outlet. This form is usually congenital in origin, and is due to non-obliteration of the processus vaginalis in infancy.

Fig. 1121.—Dissection of the Lower Part of the Abdominal Wall from within, the Peritoneum having been removed. (Wood.)



B. **Rarer form: medial, or direct.**—**Medial,** because it appears medial to the inferior epigastric artery. **Direct,** because, instead of making its way down the whole oblique canal, it comes by a short cut, as it were, only into the lower part of the canal, and then emerges by the same opening as the other.

A. **Oblique inguinal hernia.**—This possesses its coverings as follows:—

(1) **At the abdominal ring, or inlet,** it obtains three:—(*a*) Peritoneum; (*b*) extra-peritoneal fat; (*c*) infundibuliform fascia, or the vaginal process of transversalis fascia prolonged at this spot along the cord.

(2) **In the canal** it obtains one. As it emerges beneath the lower border of the internal oblique it gets some fibres from the cremaster.

(3) **At the subcutaneous ring, or outlet,** the hernia obtains three, viz.: (*a*) Intercrura fibres (intercolumnar fascia); (*b*) superficial fascia; and (*c*) skin.

B. **Direct inguinal hernia.**—This does not come through the abdominal ring, but, making its way through the posterior wall of the lower third of the canal, either through the medial or intermediate inguinal fossa. Its coverings, therefore, vary slightly with its mode of exit (*vide infra*).

Hitherto the two forms of inguinal hernia have been considered from the **superficial aspect,** that in which they are met with in practice. The inguinal region should also be studied as to the **posterior aspect** of its so-called rings and canal, as these have to bear the early stress of a commencing hernia. It is against this aspect that a piece of omentum or intestine is constantly and insidiously pressing and endeavouring to make its way out. Furthermore, when either of the above constituents of hernia have made their way a little farther, and got out into the abdominal ring or into the canal, the patient is no longer sound.

On the posterior wall are certain cords and depressions, marking off regions which correspond to those on the surface. Thus, there are three prominent **cords** and three **fossæ** (fig. 1121).

Three cords—(1) Median, or **urachus**; (2) lateral, or the **obliterated hypogastric arteries.**

(1) Median, or urachus. This interesting fœtal relic, the intra-abdominal part of the allantois, passes up between the apex of the bladder and the umbilicus.

(2) The obliterated hypogastric arteries. These, the remains of vessels which during fœtal life carry the impure blood of the fœtus out to the mother through the umbilicus, run up and join the urachus at the umbilicus.

In relation to these cords are the following **fossæ**:—(*a*) A **medial** one, between the urachus and the obliterated hypogastric artery. This corresponds, on the anterior surface, to the subcutaneous inguinal (external abdominal) ring. Through this fossa comes the commonest form of direct inguinal hernia. (*b*) Between the obliterated hypogastric artery and the inferior epigastric artery, which runs upward and medially to form the lateral boundary of Hesselbach's triangle, is **an intermediate fossa.** This is the smallest of all. The rarer form of direct hernia comes through here. (*c*) The **lateral fossa** is lateral to the inferior epigastric artery. It is the most distinct of the three, from the way in which the cord or round ligament passes down within a glove-like vaginal process of the transversalis fascia. This fossa corresponds to the abdominal ring.

The coverings of a direct hernia may now be considered, together with **the two-fold manner of exit** of this hernia. It only traverses the lower part of the canal, making its way through either the medial or the intermediate inguinal pouch. (i) The commonest form, coming through the medial inguinal pouch, either pushes its way through or stretches before it the falx inguinalis. Its *coverings* are:—(1) Peritoneum; (2) extra-peritoneal fat; (3) transversalis fascia; (4) falx inguinalis (unless this is suddenly burst through); (5) (6) (7). At the subcutaneous ring the three coverings are the same as in the oblique variety. (ii) This rarer form of direct hernia comes through the intermediate inguinal pouch. As a rule, the falx inguinalis does not reach over this fossa. The coverings will be the same as in the last, with two exceptions—there is no falx inguinalis, and the cremasteric fascia, if well developed, will be present.

Varieties of inguinal hernia according to the condition of the vaginal process of peritoneum.—Inguinal herniæ have above been classified according to their relation to the deep epigastric artery. It remains to allude to the arrangement of these same herniæ according to the varying condition of the **processus vaginalis.** This pouch of peritoneum, which paves the way for the passage of the testis before this organ makes its start, eventually becomes the parietal layer (p. 1387) of the tunica vaginalis below, in this fashion: During the first few weeks after birth the process becomes obliterated at two spots—one near the abdominal ring, and one just above the testis. The obliterative process, commencing first above and descending, and then, ascending from below, the shrivelling continues until nothing is left save the tunica vaginalis below. The following are possible hernial results of an imperfect obliteration of the process:—

(1) If the process does not close at all, a descending **hernia** is called **congenital.** This may make its way into the scrotum. The testis is now enveloped and concealed by the hernia.

(2) If the process is closed only above, i. e., near the abdominal ring, two varieties may be met with, *the infantile* and the *infantile encysted.* In the *infantile*, owing to pressure above, the weak septum gradually yields and forms a sac behind the unobliterated lower part of the processus funiculo-vaginalis. Thus three layers of peritoneum may now be met with in an operation, the two of the incompletely obliterated tunica vaginalis, and the proper sac of the hernia. In the **encysted infantile** variety the hernial pressure causes the septum to yield and form a sac projecting into, not behind, the incompletely obliterated tunica vaginalis. Here, theoretically, two layers of peritoneum will be met with. Another variety of such an encysted hernia may be produced by rupture, not stretching, of the above-mentioned septum.

(3) If the processus vaginalis be closed below and not above, a patent tubular process of peritoneum will lead down as far as the top of the testis. Any hernia into this process is called a **hernia into the funicular process.** All these varieties save the congenital and hernia into the funicular process are rare in practice. Other practical points are that all herniæ **in children and** young adults are probably of congenital origin, and, therefore, the weakness is often bilateral, though it may not be so palpably. This applies to both sexes. Again in hernia of sudden origin into the funicular process with narrow surroundings, strangulation may be very acute.

Inguinal hernia in the female.—The inguinal canal in women is smaller and narrower than in men. Inguinal hernia is, therefore, less common in the female sex, and occurs in patients who happen to be the subjects of an unobliterated processus vaginalis, which extends for a varying distance along the round ligament, and is called the canal of Nuck. Inguinal hernia in the female is, therefore, always congenital. It is, practically, always of the oblique variety, and travels along the round ligament toward the labium majus. Its coverings will be the same as those of the oblique variety in the male, save that the cremaster, as a distinct muscle, is absent, and any fibres of the internal oblique which may be present are but little developed.

FEMORAL HERNIA

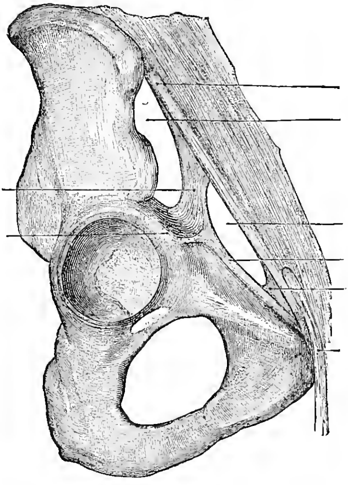
Parts concerned in femoral hernia.—(1) **Skin and superficial fascia of groin.**—The latter consists of two layers: (*a*) **Superficial layer of superficial fascia.**—Fatty, met with over the whole groin, and continuous with the superficial fascia of the rest of the body. (*b*) **Deep layer of superficial fascia.**—Thin and membranous, only met with over the lower third of the abdominal wall and to the medial side of the groin.

It is continuous through the scrotum with the deep layer of the superficial fascia of the perineum. Just below the inguinal ligament it is joined to the fascia lata. From these two facts it results that in rupture or giving way of the urethra the extravasated urine may come forward by way of the genitals (p. 1385) and from the continuity of the fascia make its way on to the abdomen, but not down on to the thigh.

Between the two layers of superficial fascia lie the superficial nodes of the groin, the superficial branches of the common femoral artery, one or two cutaneous nerves, and some veins descending to the fossa ovalis to join the great saphenous vein.

(2) **Inguinal (Poupart's) ligament.**—This is also known as the crural arch, a misnomer, as 'crus' means leg. A description of its shape and attachments is given on p. 1371. Owing to the connection of the fascia lata to its lower border, the fossa ovalis (saphenous opening), which is situated in the fascia lata, and has its upper cornu blending with the inguinal ligament, will be affected by movements of the thigh, much as is the subcutaneous inguinal (external abdominal) ring, being tightened and stretched when the limb is extended and abducted, relaxed when it is adducted and flexed.

Fig. 1122.—The Lacunæ beneath the Inguinal Ligament. (Lockwood.)



The **parts beneath the ligament** which block up the gap between it and the innominate bone are of the utmost importance in preventing the escape of a femoral hernia (fig. 1122).

The different structures are arranged in three compartments (fig. 1122), named latero-medially:—A. **lateral, iliac,** or **muscular;** B. **central,** or **vascular;** and C. **medial,** or **pectineal.** Of these, the first is the largest; the second or intermediate one lies slightly nearer to the inguinal ligament than the other two; while the medial compartment differs from the other two by not communicating with the pelvis, being closed above (*vide infra*).

(A) The **lateral,** or **iliac, compartment** is bounded in front by the inguinal ligament and the iliac fascia, which is here blending with it, behind by the ilium, laterally by this bone and the sartorius, and medially by the ilio-pectineal septum, which, descending from the blending of the iliac fascia and the inguinal ligament above, passes down to the ilio-pectineal eminence, and thence to the medial aspect of the front of the capsule of the hip-joint. This compartment transmits the ilio-psoas and femoral (anterior crural) and lateral cutaneous nerves. (B) The **vascular compartment** is bounded, in front, by the inguinal ligament and the transversalis fascia, which here blends with it, forming the so-called deep crural arch, and at the same time descends on to the front of the femoral sheath. The posterior boundary, Cooper's ligament, is formed by the meeting of the ilio-pectineal septum laterally and the pectineal fascia or sheath—medially the lacunar (Gimbernat's) ligament, and laterally the ilio-pectineal septum. This intermediate compartment transmits the ex ernal iliac vessels and the lumbo-inguinal nerve. This lies to the lateral side of the artery, the vein medially. Between the vein and the base of the lacunar ligament is the femoral canal (*vide infra*). (C) The **medial or pectineal compartment** is bounded by the pectineal fascia, continuous with the pubic part of the fascia lata, and behind by the pubic ramus. It lodges the upper end of the pectineus muscle, and the handle of a scalpel passed upward along the muscle would be prevented from passing into the pelvis by the lacunar ligament and the blending of the pectineal fascia with the upper border of the pubic ramus.

(3) **Lacunar (Gimbernat's) ligament.**—This is merely the triangular medial attachment of Poupart's ligament. Its apex is attached to the pubic tubercle; of its three borders, the base is free toward the vein and the femoral canal. Its upper border is continuous with Poupart's ligament; its lower is attached to the terminal (ilio-pectineal) line.

(4) **Fascia lata.**—Two portions are described over the upper part of the thigh:—(*a*) An **iliac,** lateral and stronger, attached to the inguinal ligament in its whole extent and lying over the sartorius, ilio-psoas, and rectus. (*b*) A **pubic,** medial, weaker, and much less well defined, is attached above to the terminal line and the tubercle of the pubes. The upper cornu of the fossa ovalis is at the lacunar ligament, and at the lower cornu the two portions of the fascia blend.

Their relation to the femoral vessels.—The iliac portion, being attached along Poupart's ligament, passes over these. The pubic portion, fastened down over the pectineus, which slopes down on to a deeper plane than the adjacent muscles, passes behind the femoral vessels to end on the capsule of the hip-joint.

(5) **Fossa ovalis (saphenous opening).**—This is not an opening, but an oval depression, situated at the spot where the two parts of the fascia lata diverge on different levels. Though the fascia lata is wanting here, there is no real opening, as the deficiency is made up by the deep layer of superficial fascia, or cribriform fascia, which fills up the opening.

Uses of the fossa ovalis (*saphenous opening*).—Though a weak spot, it is so on purpose to transmit the saphenous to the femoral vein, and the superficial to the deep lymphatics. The depression is present in order to allow the saphenous vein to be protected from pressure in flexion of the thigh.

Site.—At the medial and upper part of the thigh, with its centre 3.7 cm. ($1\frac{1}{2}$ in.) below and lateral to the tubercle of the pubis.

Diameters.—Vertically, 2.5 cm. (1 in.), by 1.2 or 1.8 cm. ($\frac{1}{2}$ or $\frac{3}{4}$ in.). *Shape:* oval, with its long axis downward and laterally. *Two extremities* or *cornua:* upper blending with the lacunar ligament; lower, where the two parts of the fascia lata meet. *Two borders:* lateral or falciform, also known as the ligament of Hey, or femoral ligament. Semilunar in shape, arching downward and laterally from the lacunar ligament to the inferior cornu. This lies over the femoral vessels, and is adherent to them; to it is fixed superficially the cribriform fascia (*vide infra*). The medial border is much less prominent, owing to the weakness of the pubic part of the fascia lata which forms it.

(6) **Femoral sheath.**—This is a funnel-shaped sheath, carried out by the femoral vessels under Poupart's ligament, and continuous above (in front) with the transversalis fascia as it descends to the ligament, lining the inner surface of the abdominal wall; and (behind) with the iliac fascia, and below continuous with the proper sheath of the femoral vessels.

It is not only funnel-shaped, but large and loose, for two reasons:—(*a*) That there be plenty of room for the femoral vein and the slowly moving venous current in it to ascend without compression; (*b*) to allow all the movements of the thigh taking place—flexion and extension—without undue stretching of the vessels. By two connective-tissue septa the sheath is divided into three compartments—the lateral for the artery, the intermediate for the vein, and the medial one for the femoral canal (*vide infra*). Thus one septum lies between the artery and vein, and another between the vein and the femoral canal.

(7) **Femoral canal.**—Definition: the medial division of the femoral sheath. The fascia transversalis and fascia iliaca meet directly on the lateral side of the femoral artery, but not so closely on the medial side of the femoral vein. Hence a space exists here, perhaps to prevent the thin-walled vein, with its sluggish current, being pressed upon, but it is merely a slight gap—not a canal, unless so made by a knife or by the dilating influence of a hernia.

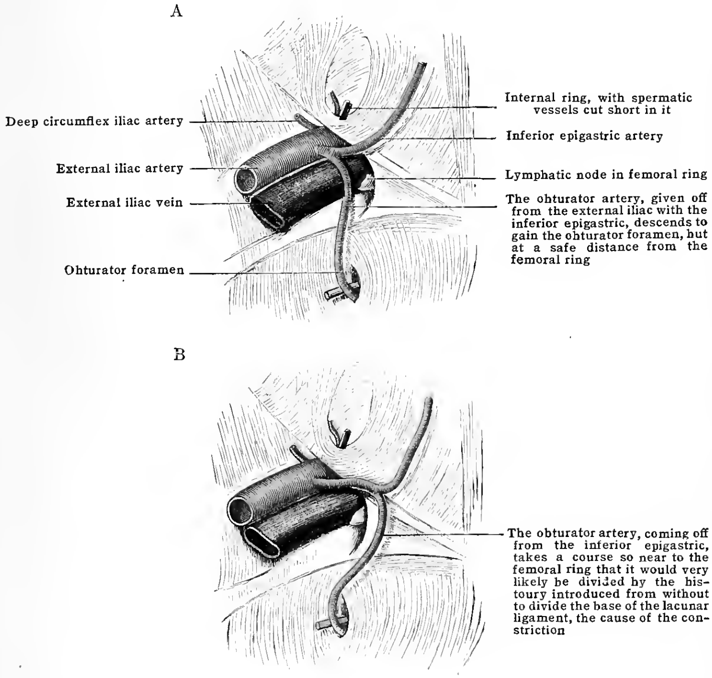
Length: about 1.9 cm. ($\frac{3}{4}$ in.). *Limits:* below, fossa ovalis; above, femoral ring (*vide infra*).

Boundaries.—Laterally, a septum between it and the vein; medially, base of the lacunar ligament and meeting of fascia iliaca and transversalis; behind, fascia iliaca; in front, fascia transversalis.

Contents.—Cellular tissue and fat, continuous with extra-peritoneal fatty layer. A lymphatic node, which is inconstant. Lymphatics passing from inguinal nodes to those in the pelvis.

(8) **Femoral ring.**—This is mainly an artificial product. It is the upper or abdominal opening of the femoral canal. *Shape:* oval, with its long axis transverse. It is larger in women. *Boundaries:* medially, the lacunar ligament; laterally, the femoral vein; in front, the inguinal ligament and the thickening of the transversalis fascia attached to it, and called 'the deep crural arch'; behind the pectineus and Cooper's ligament, a thickened fascial bundle attached

Fig. 1123.—Irregularities of the Obturator Artery. (After Gray.)



to the linea terminalis (fig. 1122). It is closed by the septum crurale, which is a barrier of fatty connective tissue, continuous with the extra-peritoneal fatty layer, perforated by lymphatics passing upward to the pelvic nodes.

Position of vessels around the ring.—Laterally the femoral vein; above, the epigastric vessels as they ascend from the external iliac vessels, pass close to the upper and lateral aspect of the ring; immediately in front are the cord and spermatic vessels always to be remembered in this hernia in the male; toward the medial side there may be an unimportant anastomosis between the epigastric artery above and the obturator below.

If from dilatation of the above anastomosis the obturator artery comes off abnormally from the inferior epigastric, it will descend, and usually does so, close to the junction of the external iliac and common femoral vein, and thus to the lateral and so the safe, side of the ring (fig. 1123, A). In a very few cases it curves more medially, close to the lacunar ligament, and thus to the medial side of the ring, and is then in great danger (fig. 1123, B). In two out of every five cases the obturator arises from the inferior epigastric. In about thirty-seven per cent. of the cases with such an origin the artery either crosses or courses along the side of the ring. (Cunningham.)

Course of femoral hernia.—At first this is downward in the femoral canal. A pouch of peritoneum having been gradually, after repeated straining, coughing, etc., pushed through the weak spot, the femoral ring, further weakened perhaps, together with all the parts in the femoral arch, by child-bearing, some extra effort will force intestine or omentum into this pouch and thus form a hernia. Thus formed, femoral hernia passes at first downward in the femoral canal as far as the fossa ovalis, but, as a rule, does not go farther downward on the thigh, but mounts forward and upward, and somewhat laterally, even reaching the level of the inguinal ligament. The reasons for this change of position are:—(1) The narrowing of the femoral sheath, funnel-like, i. e., wide above, but narrowed below; (2) the unyielding nature of the lower margin of the fossa ovalis; (3) the fact that this margin and the lateral border are united to the femoral sheath; (4) the constant flexion of the thigh; (5) the fact that vessels (chiefly veins) and lymphatics descend to the fossa ovalis, the veins to join the saphenous vein and the lymphatics to join the deeper group; these descending vessels serve to loop upward or suspend a femoral hernia, and thus prevent its further course downward.

Coverings of a femoral hernia.—(A) **At the upper** or **femoral ring** it obtains peritoneum, extra-peritoneal fat, and septum femorale (crurale).

(B) **In the canal,** a coating of the femoral sheath.

(C) **At the external opening,** further coverings of cribriform fascia, skin, and superficial fascia are added.

Some of these may be deficient by the hernia bursting through them, or they may be matted together. Sir A. Cooper thought this especially likely to occur with the layer of femoral sheath and septum crurale, to which he gave the name of *fascia propria.*

The relations of an inguinal and femoral hernia respectively to the pubic tubercle are of importance in distinguishing between them clinically. If a finger is placed on the pubic tubercle a hernia that lies above and medial to it will be inguinal, one below and lateral to it will be femoral.

Radical cure of femoral hernia.—The close proximity of the femoral vein always introduces difficulty in the introduction of the deep sutures for closure of the crural ring. Any closure below this point is certain to be inefficient. The safest and simplest method is to feel for the pulsation of the femoral artery, and make allowance for the vein on its medial side. The latter vessel is then protected by the finger-tip passed up the femoral canal, so that its dorsum rests against the vein and its tip upon the linea terminalis. The sutures are then passed so as to pick up the ilio-pectineal fascia and its thickened part, Cooper's ligament, below, and the deep crural arch and Poupart's ligament above (fig. 1122). Thus, when tightened, they draw the anterior and posterior boundaries of the ring together. (Lockwood, Bassini.)

PARTS CONCERNED IN UMBILICAL HERNIA

A hernial protrusion at the umbilicus, or exomphalos, may occur at three distinct periods of life, according to the anatomy of the part. Any account of umbilical hernia would be incomplete without an attempt to explain how this region, originally a most distinct opening, is gradually closed and changed into a knotty mass of scar, the strongest point in the abdominal wall.

During the first weeks of fœtal life, in addition to the urachus, umbilical arteries, and vein, some of the mesentery and a loop of the intestine pass through the opening to occupy a portion of the body cavity situated in the umbilical cord, later on returning to the abdominal cavity. Occasionally this condition persists, owing to failure of development, and the child is born with a large hernial swelling outside the abdomen, imperfectly covered with skin and peritoneum. To this condition the term **congenital umbilical hernia** should be applied.

Later on in fœtal life it is the umbilical vessels alone which pass through this opening. At birth there is a distinct ring, which can be felt for some time after in the flaccid walls of an infant's belly. If this condition persist, a piece of intestine may find its way through, forming the condition which should be known as **infantile umbilical hernia.**

This condition is not uncommon. Why it is not more frequently met with is explained by the way in which this ring of infancy is closed and gradually converted into the dense mass of scar tissue so familiar in adult life. This is brought about—(1) by changes in the ring itself; (2) by changes in the vessels which pass through it.

(1) **Changes in the ring itself.**—The umbilical ring is surrounded by a sphincter-like arrangement of elastic fibres, best seen during the first few days of extra-uterine life, on the

posterior aspect of the belly wall. In older infants these fibres lose their elasticity, become more tendinous, and then shrink more and more. As they contract they divide, as by a ligature, the vessels passing through the ring, thus accounting for the fact that the cord, wherever divided, drops off at the same spot and without bleeding.

(2) **Changes in the vessels themselves.**—When blood ceases to traverse these, their lumen contains clots, their muscular tissue wastes, while the connective tissue of their outer coat hypertrophies and thickens. Thus, the umbilical vessels and the umbilical ring are, alike, converted into scar tissue, which blends together. This remains weak for some time, and may be distended by a hernia (infantile).

Finally, we have to consider the state of the umbilicus in adult life. The very dense, unyielding, fibrous knot shows two sets of fibres:—(1) Those decussating in the middle line; and (2) two sets of circular fibrous bundles which interlace at the lateral boundaries of the ring. The lower part of the ring is stronger than the upper. In other words, **umbilical hernia of adult life**, when it comes through the ring itself and not at the side, always comes through the upper part. In the lower three-fourths of the umbilicus the umbilical arteries and urachus are firmly closed by matting in a firm knot of scar tissue; in the upper there is only the umbilical vein and weaker scar. To the lower part run up the umbilical arteries and the urachus. Owing to the rapid growth of the abdominal wall and pelvis before puberty, and the fact that the urachus and the umbilical arteries, being of scar tissue, elongate with difficulty, the latter parts depress the umbilicus by reason of their intimate connection with its lower half.

Owing to the usual exit of an umbilical hernia of adult life being through the upper part of the ring, the constricting edge in strangulation should be sought below and divided downward. As pointed out by Mr. Wood, it is here that the dragging weight of the hernial contents and the weight of the dress tend to produce the chief results of strangulation. An incision here also gives better drainage if required.

Coverings of an umbilical hernia.—These, more or less matted together, are:—(1) Skin; (2) superficial fascia, which loses its fat over the hernia; (3) prolongation of scar tissue of the umbilicus gradually stretched out; (4) transversalis fascia; (5) extra-peritoneal fatty tissue; (6) peritoneum. If the hernia come through above the umbilicus, or just to one side, the coverings will be much the same; but, instead of the layer from the umbilical scar, there will be one from the linea alba.

Strangulated umbilical hernia of adult life.—In this, the most fatal of the strangulated herniæ ordinarily met with, the following are practical points in the surgical anatomy:—1. The coverings, including the sac, are always thin, at times so markedly so that the intra-peritoneal contents are practically subcutaneous. 2. The sac is multilocular, and one or more of its chambers may lie very deep. 3. The contents are numerous, viz., omentum, often voluminous and adherent, transverse colon, and later in the history, small intestine. 4. The contents are often adherent to the sac and each other, thus explaining the irreducibility. 5. The long duration of the presence of the transverse colon with its stouter walls accounts for the period, often prolonged, in which warning evidence of incarceration precedes that of strangulation. 6. The communication with the peritoneal sac is direct, short, and during a prolonged operation, free. Infection is thus readily brought about.

THE BACK

The surface form and landmarks of the back will be considered first, followed by the relations of skeleton, muscles, viscera and nervous system.

Median furrow.—This is more or less marked according to the muscular development, lying between the trapezii and semispinales capitis, in the cervical region, and the sacro-spinales lower down. The lower end of the furrow corresponds to the interval between the spines of the last lumbar and the first sacral vertebræ. (Holden.)

Vertebral spines.—Those of the upper cervical region are scarcely to be made out even by deep pressure. That of the axis may be detected in a thin subject. Over the spines of the middle three cervical vertebræ is normally a hollow, owing to these spines receding from the surface to allow of free extension of the neck. The seventh cervical is prominent, as its name denotes. Between the skull and atlas, or between the atlas and epistropheus, a pointed instrument might penetrate, especially in flexion of the neck.

Of the **thoracic spines**, the first is the most prominent, more marked than that of the last cervical; the third should be noted as on a level with the medial end of the scapular spine, and in some cases with the bifurcation of the trachea; that of the seventh with the lower angle of the scapula; that of the twelfth with the lowest part of the trapezius and the head of the twelfth rib. The obliquity and overlapping of the thoracic spines are to be remembered.

Of the **lumbar spines**, the most important are the second, which corresponds to the termination of the cord, and the fourth, which marks the highest part of the iliac crests and the bifurcation of the abdominal aorta. The lumbar spines project horizontally, and correspond with the vertebral bodies. The third is a little above the umbilicus.

Owing to the obliquity of the thoracic spines, most of them do not tally with the heads of the corresponding ribs. Thus, the spine of the second corresponds with the head of the third rib; the spine of the third with the head of the fourth rib; and so on till we come to the eleventh and twelfth vertebræ, which do tally with their corresponding ribs. (Holden.)

The lower ribs may be felt lateral to the sacro-spinalis but in counting them from below it must be remembered, as pointed out by Holl, that in quite a

FIG. 1124.—DIAGRAM AND TABLE SHOWING THE APPROXIMATE RELATION TO THE SPINAL NERVES OF THE VARIOUS MOTOR, SENSORY, AND REFLEX FUNCTIONS OF THE SPINAL CORD. (Arranged by Dr. Gowers from anatomical and pathological data.)

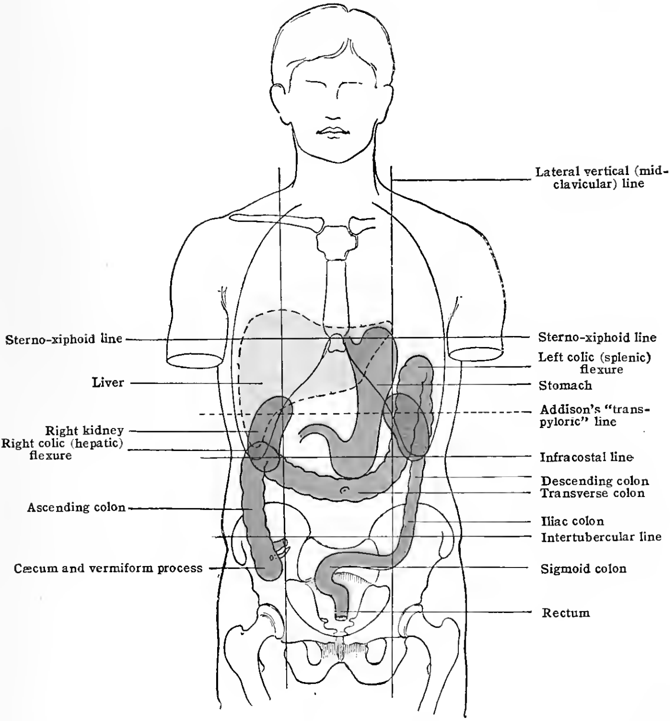
5			
Co.		Skin from coccyx to anus	

considerable percentage the last rib is so abnormally short that it does not reach as far as the lateral border of the sacro-spinalis; or is so rudimentary as to resemble a transverse process (consequently the only safe method of counting ribs is from above). In these cases the lower end of the pleura may pass from the lower part of the twelfth thoracic vertebra, almost horizontally to the lower edge of the eleventh rib.

Muscles.—The student will remember the greater number and complexity and the numerous tendons of the muscles which run up on either side of the spines; the firmness and inextensibility of their sheaths; the large amount of cellular tissue between them; and the fact that toward the nape of the neck these muscles lie exposed instead of being protected in gutters, as is the case below: all these anatomical points explain the extreme painfulness and obstinacy of sprains here.

Trapezius.—To map out this muscle, the arm should be raised to a right angle with the trunk. The external occipital protuberance should be dotted in, and the superior nuchal line passing out from this; below, the twelfth thoracic spine should be marked; and laterally, the lateral third of the clavicle and the commencement of the scapular spine. Then a line should be drawn from the protuberance vertically downward to the twelfth thoracic spine; a second from about the middle of the superior nuchal line to the posterior and lateral third of the clavicle; and a third from the last thoracic spine upward and laterally to the root of the spine of the scapula.

Fig. 1125.—Relations of the Abdominal Viscera to the Anterior Body Wall.



Latissimus dorsi.—The arm being raised above a right angle, the spines of the sixth thoracic and the third sacral vertebræ should be marked; then the outer lip of the crest of the ilium, the lower two or three ribs, the lower angle of the scapula, and the posterior fold of the axilla, and finally the intertubercular (bicipital) groove should all be marked.

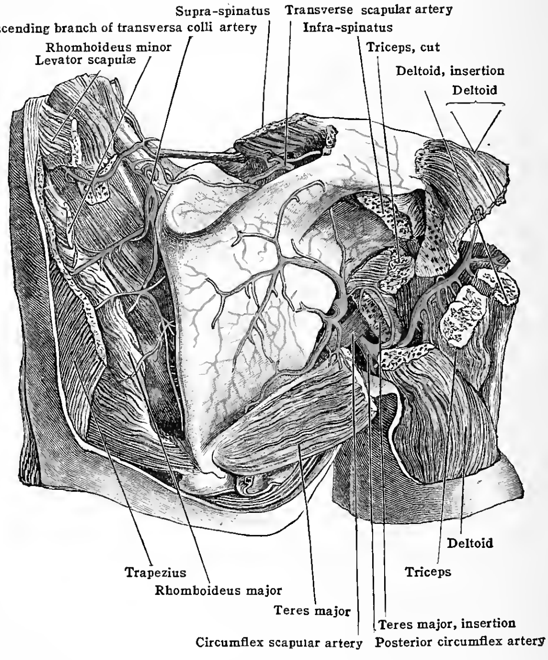
A vertical line from the sixth thoracic to the third sacral spine will give the spinal origin of the muscle. Another from the third sacral spine to a point on the iliac crest, 2.5 cm. (1 in.) or more lateral to the edge of the sacro-spinalis, will give the origin of the muscle from the sheath of the sacro-spinalis and the ilium. A line from the sixth thoracic spine, almost transversely at first, with increasing slight obliquity over the inferior angle of the scapula to the axilla and intertubercular groove, will mark the upper border of the muscle. Another very oblique line from the point of the iliac crest upward and laterally to the axilla will give the lower border and the tapering triangular apex of the insertion. The muscle may be attached to the angle of the scapula, or separated from it by a bursa.

Triangle of Petit.—This small space lies above the crest of the ilium, at about its centre, bounded by the anterior edge of the latissimus behind and the posterior border of the external oblique, in front. Through this gap, when the muscles are weak, a lumbar abscess occasionally, and very rarely, a lumbar hernia, may appear.

Origin of spinal nerves.—It is very important to remember the relations of these to the vertebral spines, in determining the results of disease or injury of the cord and the parts thereby affected. The above relations may be given briefly as follows:—

The origins of the eight cervical nerves correspond to the cord between the occiput and the sixth cervical spine. The upper six thoracic come off between

Fig. 1126.—Chief Arterial Anastomoses on the Scapula.
(From a dissection in the Hunterian Museum.)



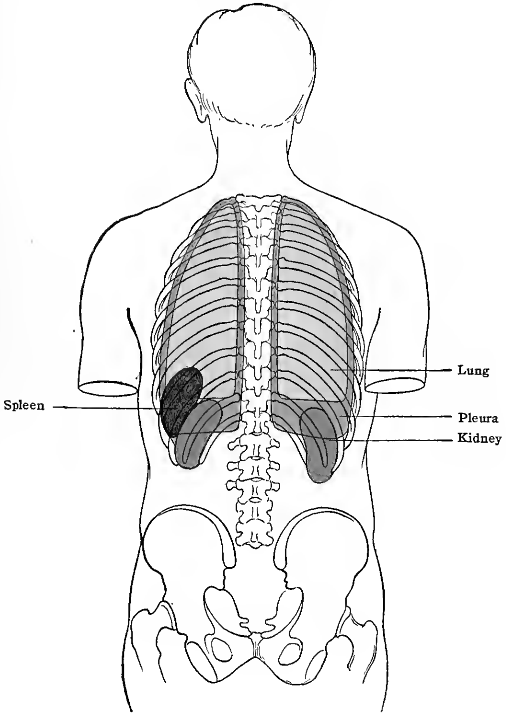
the above spine and that of the fifth thoracic vertebra. The origins of the lower six thoracic nerves correspond to the interval between the fourth and the tenth thoracic spines. The five lumbar arise opposite the eleventh and twelfth thoracic spines; and the origins of the five sacral correspond to the first lumbar spines. The diagram and table (fig. 1124), arranged by Dr. Gowers from anatomical and pathological data, show the relations of the origins of the nerves to their exits from the vertebral canal, and the regions supplied by each.

Scapula, its muscles and arterial anastomoses.—Amongst the landmarks in the back, the student should be careful to trace the angles and borders of the scapula as far as these are accessible. The upper border is the one most thickly covered. With the hands hanging down, the upper (medial) angle corresponds to the upper border of the second rib; the lower angle to the seventh intercostal space; and the root of the spine of the scapula to the interval between the third and fourth thoracic spines.

The axillary border of the scapula, covered by the latissimus dorsi and teres major, may best be palpated with the arm hanging to the side. The vertebral border is brought into prominence by placing the hand on the opposite shoulder. This border is held in apposition with the thorax by the serratus anterior; consequently in paralysis of that muscle, supplied by the long thoracic nerve (5, 6, and 7 C.), it becomes unduly prominent, giving rise to "winged scapula." Fig. 1126 shows the chief arteries around the scapula. The anastomoses on the acromial process between the transverse scapular (supra-scapular) thoraco-acromial, and circumflex humeral arteries are not shown. The numerous **points of ossification,** primary and secondary, by which this bone is developed explain, in part, the frequency of cartilaginous and other growths here.

The anatomy of the loin behind, the **ilio-costal region,** is of prime importance, owing to the numerous operations here. **The lateral border of the sacro-spinalis and quadratus lumborum** may be indicated on the surface thus. (Stiles.) That of the sacro-spinalis by drawing a line from a point on the iliac crest 8.2 cm. (3½ in.) (four fingers'-breadth) from the middle line upward and slightly laterally to the angles of the ribs. That of the quadratus passing upward and slightly medially lies a little lateral to that of the sacro-spinalis (erector) at the crest,

FIG. 1127.—RELATIONS OF THE ABDOMINAL VISCERA TO THE POSTERIOR BODY WALL.



and a little medial to it at the twelfth rib. The ascending and descending colon lie in the slightly depressed angle between the two muscles. The ilio-costal region varies greatly in space according to the length of the lower ribs, shape of the chest, and development of the iliac crest. An incision here—that for exploration of the kidney may be taken as the type—would be an oblique one, about 10 cm. (4 in.) long, starting in the angle between the twelfth rib and the sacro-spinalis muscle and passing forward and downward toward the anterior extremity of the iliac crest. In its upper part the incision should lie 1.2 cm. (½ in.) below the tweltfh rib. The anterior fibres of the latissimus dorsi are divided behind, the posterior ones of the external oblique in front. The yellowish-white lumbar fascia now comes into view, and is the first important landmark. It and the fibres of the internal oblique and transversus which arise from it are next carefully divided. The last thoracic nerve and lowest intercostal artery may also require division. If the latter is cut close to the rib, the hæmorrhage is troublesome. The transversalis fascia remains to be divided. To avoid the peritoneum, the deeper part of the incisions should always be made from behind forward. If more room is required, as in large growths or in exploration of the ureter, the incision must be prolonged beyond the iliac crest, the lumbo-ilio-inguinal incision of Morris.

Viscera.—Several of these, which can be mapped in behind—viz., the kidneys, spleen, etc.—have been already mentioned (pp. 1375, 1379).

The commencement of the **trachea** and **œsophagus** has been given in front as corresponding to the sixth cervical vertebra. If examined from behind, this point, owing to the obliquity of the spines, would be a little lower down. The **trachea,** about 12.5 cm. (5 in.) long, descending in the middle line, bifurcates opposite to the interval between the third and fourth thoracic spines (or fourth and fifth bodies). The **bronchi** enter the lungs at about the level of the fifth thoracic spine, the right being the shorter, wider, and more horizontal. The **root of the lung** is opposite to the fourth, fifth, and sixth dorsal spines, midway between these and the vertebral border of the scapula. The structures in it are the bronchus, pulmonary artery, two pulmonary veins, bronchial vessels, lymphatics, and nerves. The phrenic nerve is in front, the posterior pulmonary plexus behind. On the *right* side the superior vena cava is in front, the vena azygos (major) arching over the root at the level of the fourth thoracic vertebra. On the *left* side the aorta arches over the root, and the thoracic aorta descends behind it. The **œsophagus,** about 25 cm. (10 in.) in length, starting in the middle line, curves twice to the left, at first gradually at the root of the neck; from this point it tends to regain the middle line up to the fifth thoracic vertebra; thence finally turns again, and more markedly to the left, and passes through the diaphragm opposite to the tenth, entering the stomach here or at the eleventh thoracic vertebra (ninth or tenth thoracic spine). In the thorax this tube traverses first the superior, then the posterior, mediastinum. At three spots, i. e., its commencement, where it is crossed by the left bronchus, and at the cardiac orifice, it presents narrowings. The relations of this tube to the pleura, pericardium, aorta, vagi, and thoracic duct are important in the ulceration of malignant disease and infected bodies, and in the passage of instruments.

The **aorta** reaches the left side of the vertebral column, with its arch just above the fourth thoracic spine, and thence descends on the front of the column, with a slight tendency to the left, to bifurcate opposite the fourth lumbar spine.

The spinal cord.—This, about 45 cm. (18 in.) long, extends from the foramen magnum to the junction between the first and second lumbar vertebræ. Up to the third month of fœtal life it reaches to the sacral end of the vertebral canal; later, owing to the more rapid growth of the bony wall, its lower limit is at birth opposite the third lumbar vertebra. The dura mater is continued, as a sheath, as low as the second sacral vertebra. It is anchored above to the upper cervical vertebræ and the foramen magnum, and below, as the filum terminale, to the periosteum of the coccyx. The deficiency of the spinous processes and laminæ of the fourth and fifth pieces of the sacrum allows of infection, e. g., of a bed-sore reaching the membranes, and so the cord. The arachnoid and pia of the cord are continuous above with those of the brain.

The parts of the column most exposed to injury are the thoraco-lumbar and cervico-thoracic partly because here more mobile parts are joined to those which are more fixed, and also from the amount of leverage exerted on the thoraco-lumbar region, and, in the case of the upper region, because this is affected by violence exerted on the head. *The chief provisions for protection of the cord* are the number of bones and joints which allow of movement without serious weakening, the three curves and columns, cervical, thoracic, and lumbar, ensuring bending before breaking; the large amount of cancellous tissue and the number and structure of the intervertebral discs all tending to damp vibrations; the large size of the theca vertebralis and the way in which the cord, anchored and slung by the thirty-one pairs of nerves and the ligamenta denticulata, about twenty in number, occupies neutral ground in the centre of the canal as regards injury directly and indirectly applied.

In **lumbar puncture** (Quincke) as a means of diagnosis or of relieving pressure advantage is taken of the fact mentioned above that the theca extends below the cord.

A line drawn joining the highest points of the iliac crests crosses the fourth lumbar spine. The needle is inserted in the median line between the third and fourth or the fourth and fifth spines, and directed forward and slightly upward. The back must be flexed as fully as possible in order to widen the interspinous spaces. The needle is passed to a depth of about 5 cm. (2 in.) in an adult, or 1.8 cm. ($\frac{3}{4}$ in.) in an infant. In the supine position the lowest part of the subarachnoid space is in the mid-thoracic region, and an anæsthetic fluid, non-diffusible and of a higher specific gravity than the cerebro-spinal fluid, will tend to gravitate there (Barker). The level of the anæsthesia can be varied by raising the pelvis or the shoulders to different levels.

The following table, from Holden and Windle, with additions, will be found very useful in determining the relation of numerous viscera and other structures to the bodies of the vertebræ.

VERTEBRAL LEVELS

Cervical

First. Level of hard palate.

Second. Level of free edge of upper teeth.

Second and third. Superior cervical ganglion of sympathetic.

Fourth. Hyoid bone. Upper aperture of larynx.

Fifth. Thyreoid cartilage and rima glottidis. Between this and the last would be the bifurcation of the common carotid.

Sixth. Cricoid cartilage. Ending of pharynx and larynx. Consisting of the fused fifth and sixth ganglia, the middle cervical ganglion is usually opposite this vertebra. Here the omo-hyoid crosses the common carotid, and at this spot, the seat of election, the centre of the incision for tying this vessel is placed. At this level the inferior thyreoid passes behind the carotid trunk.

Seventh. Inferior cervical ganglion. Apex of lung. Arch of thoracic duct over apex of lung, outward and downward to termination.

Thoracic

First. Summit of arch of subclavian. (Godlee.) The height of this varies. Usually it is from 1.2 to 2.5 cm. (½ to 1 in.) above the clavicle. It is always in close relation with the cervical pleura.

Second. Level of episternal notch. This is usually opposite the fibro-cartilage between the second and third. Bifurcation of innominate. (Godlee.)

Third. Beginning of superior cava, at junction of first right costal cartilage with sternum. Highest part of aortic arch, about 2.5 cm. (1 in.) below notch.

Fourth. Bifurcation of trachea. Second piece of aortic arch, extending from upper border of second right costal cartilage, reaches spine. Arch of vena azygos. The superior mediastinum is bounded behind by the upper four thoracic vertebræ. Louis' angle, junction of manubrium and gladiolus. Thoracic aorta begins.

Fifth to ninth. Base of heart.

Sixth. Pulmonary and aortic valves, opposite third left costal cartilage at its sternal junction, in front. Commencement of aorta and pulmonary artery. End of superior cava, third right chondro-sternal junction in front.

Seventh. Mitral orifice.

Eighth. Tricuspid orifice.

Ninth. Lower level of manubrium and sterno-xiphoid line (at lower border). Opening in diaphragm for inferior vena cava (lower border).

Tenth. Level of tip of xiphoid cartilage. Lower limit of lung posteriorly. Upper limit of liver comes to the surface posteriorly. Œsophagus passes through diaphragm. Cardiac orifice of stomach (sometimes). Upper limit of spleen.

Eleventh. Lower border of spleen. Suprarenal gland. Cardia (sometimes).

Twelfth. Lowest part of pleura. Aorta passes through diaphragm (lower border). Cœliac artery (lower border). Upper end of kidney.

Lumbar

First. Superior mesenteric arteries. Pancreas. Pelvis of kidney. Renal arteries. Transpyloric line. (Addison.)

Second. Spinal cord ends at junction of first and second. Duodeno-jejunal flexure. Receptaculum (cisterna) chyli. Lower end of left kidney.

Third. Umbilicus, opposite disc between third and fourth. Lower end of right kidney.

Fourth. Bifurcation of aortic arch. Highest part of iliac crest.

Fifth. Commencement of superior vena cava.

Sacral

Third. End of pelvic colon and beginning of first piece of rectum proper. Lower limit of spinal membranes.

Fifth. Reflexion of recto-vesical pouch of peritoneum 2.5 cm. (1 in.) above base of prostate.

Coccyx (tip). 2.5 cm. (1 in.) below this commencement of anal canal. Termination of filum terminale.

THE UPPER EXTREMITY

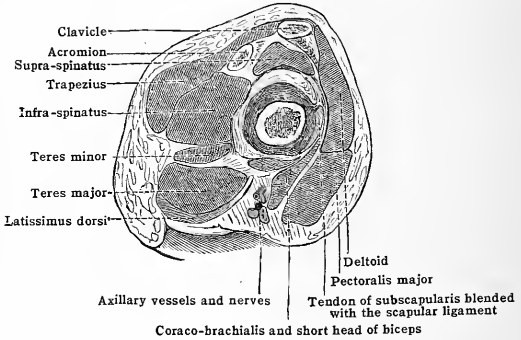
THE SHOULDER AND ARM

The surface form and landmarks of the upper extremity will first be considered followed by the various regions of the shoulder, arm, forearm and hand.

General surface form. Landmarks.—The following **surface-marks,** of the greatest importance in determining the nature of shoulder injuries, can be made out here:—The **clavicle** in its whole extent, the **acromion process,** the **great tuberosity,** and **upper part of the shaft of the humerus.** Much less distinctly, the position of the **coracoid process** in the infraclavicular fossa and the **head of the humerus** through the axilla can be made out. The anterior margin of the **clavicle,** convex medially and concave laterally, can be made out in its whole extent, the bone, if traced laterally, being found not to be horizontal, but rising somewhat to its junction with the acromion. The **sterno- and acromio-clavicular joints** have been referred to at p. 1363.

The *frequency of fracture of the clavicle* is explained chiefly by its exposure to shocks of varied kinds from the upper extremity, inseparable from the out-rigger-like action of the bone and its early ossification. On the other hand, *the main safeguards* are the elasticity and curves of the bone, the way in which it is embedded in muscles which will damp vibrations, and the buffer-bond fibro-cartilages at either extremity. The looseness and toughness of the overlying skin explain the rarity of compound fracture here. The junction of the two curves is the weakest spot and the usual site of fracture. The weight of the limb acting through the coraco-clavicular ligaments and overcoming the trapezius is the chief factor in the downward displacement; the pectoralis minor and serratus anterior acting on the scapula draw the acromial fragment forward. The tip of the *acromion,* when the arm hangs by the side with the hand supinated, is in the same line as the lateral condyle and the styloid process of the radius. On the medial side, the head and medial condyle of the humerus and the styloid process of the ulna are in the same line. Thus the *great tuberosity* looks laterally, the *head* medially, and the *lesser tuberosity* somewhat forward. Between the two tuberosities runs the **intertubercular (bicipital) groove,** which,

FIG. 1128.—TRANSVERSE SECTION THROUGH THE RIGHT SHOULDER-JOINT, SHOWING THE STRUCTURES IN CONTACT WITH IT. (Braune.)



with the arm in the above position, looks directly forward. In thin subjects its lower part can be defined. Its position can be marked with sufficient accuracy by a line running downward from the acromion in the loug axis of the humerus. Besides the tendon and its synovial sheath, the insertion of the latissimus dorsi, the humeral branch of the thoraco-acromial artery, and the anterior circumflex artery run in the groove. When the fingers are placed on the acromion and the thumb in the axilla, the lower edge of the glenoid cavity can be felt; and if the humerus be rotated (the elbow-joint being flexed), the head of the humerus can be felt also.

The **characteristic roundness of the shoulder** is due to the great tuberosity lying under the deltoid (fig. 1130). In dislocation the loss of this roundness is due to the absence of the head and tuberosity and consequent projection of the acromion.

This normal projection of the deltoid renders it impossible to place a flat straight body in contact with both the acromion and the lateral epicondyle at the same time (Hamilton's dislocation test). Below the junction of the lateral and middle thirds of the clavicle, between the contiguous origins of the pectoralis major and deltoid, is the infraclavicular fossa, in which lie the cephalic vein, the deltoid branch of the thoraco-acromial artery, and a lymphatic node which may be involved in obstinate tuberculosis of the cervical groups. On pressing deeply here, the coracoid process can be made out if the muscles are relaxed, and the axillary artery compressed against the second rib.

On raising the arm and abducting it, the different parts of the **deltoid** can often be made out —viz., fibres from the lower border of the spine of the scapula, the lateral edge of the acromion, and the lateral third or more of the front of the clavicle; the characteristic knitting of the surface owing to the presence of fibrous septa continuous, alike, with the skin and the sheath of the muscle and the tendinous septa which separate the muscular bundles, will also be seen. The muscle will be marked out by a base-line reaching along the above bony points, and two sides converging from its extremities to the apex, a point on the lateral surface of the humerus, about its centre. In paralysis of the deltoid, the humerus being no longer braced up against the scapula, the finger-tips can be placed between it and the acromion.

To map out the **pectoralis major,** a line should be drawn down the lateral aspect of the sternum as far as the sixth costal cartilage, and then two others marking the borders of the muscle—the upper corresponding to the medial border of the deltoid, the lower starting from the sixth cartilage, and the two converging to the folded tendon, which is inserted as a double

Fig. 1129.—The Shoulder-joint, as shown by the Röntgen-rays.

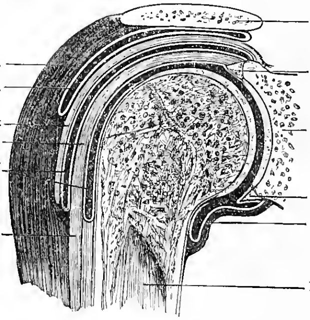
layer into the lateral tubercular (bicipital) ridge. The **pectoralis minor** will be marked out by two lines, from the upper border of the third and the lower border of the fifth rib, just lateral to their cartilages, and meeting at the coracoid process. The lower line gives the level of the long thoracic artery; the upper, where it meets the line of the axillary artery, that of the thoraco-acromial.

When the arm is abducted and the humerus rotated a little laterally, the prominence of a well-developed **coraco-brachialis** comes into view; a line drawn from the centre of the clavicle along the medial border of this muscle to its insertion into the humerus gives the line of the axillary artery.

Axillary fossa.—The boundaries of this space anterior, posterior, medial, or thoracic, lateral or humeral, apex and base, with the structures forming them and the vessels and nerves in relation to them, must be remembered. The chief vessels are the axillary on the lateral wall, brought into prominence when the arm is abducted, as in removal of the mamma, and the subscapular on the posterior wall. The apex is felt, when the finger is pushed upward in an operation here, to be bounded by the clavicle in front, the first rib behind, and the coracoid somewhat laterally. The base is concave, owing to the coraco-clavicular (costo-coracoid) membrane as it descends to blend with the sheath of the pectoralis minor, giving also a process to the axillary fascia which unites the anterior and posterior boundaries. This process also sends septa to the skin.

An **axillary abscess**, always to be opened early to avoid subsequent interference with the movements of the shoulder, is reached by an incision on the medial wall, midway between the anterior and posterior boundaries, so as to avoid the long thoracic and subscapular vessels, respectively, the back of the knife being directed toward the lateral wall. The only vessel on this wall is the superior thoracic, which lies high up. Additional safety is given by the use of Hilton's method. For **exploration** of the axilla the best incision is an angular one, the two limbs being placed in a line with the anterior margin of the great pectoral, and in the line of the axillary vessels. This runs from a point on the centre of the clavicle (the limb being at a right angle to the trunk) to the medial margin of the coraco-brachialis. If this be obliterated by swelling, the above line should be prolonged to the middle of the bend of the elbow, which will give the guide to the brachial also. **Collateral circulation.** If the first part of the artery be tied, the channels are the same as in ligature of the third part of the subclavian (*q.v.*). In ligature of the third part of the axillary, if the ligature be *above* the circumflex arteries, the chief vessels concerned are the transverse scapular (suprascapular) and thoraco-acromial above and the

FIG. 1130.—DIAGRAMMATIC SECTION OF SHOULDER THROUGH THE INTERTUBERCULAR (BICIPITAL) GROOVE. (Anderson.)



posterior circumflex below. If the ligature be *below* the circumflex, the anastomoses will be those concerned in ligature of the brachial above the profunda (p. 1414). The lymphatic nodes in the axilla have been mentioned at p. 719, (fig. 566).

The depression of the **axillary fossa** is best marked when the arm is raised from the side to an angle of about 45°, and when the muscles bounding it in front and behind are contracted. In proportion as the arm is raised, the hollow becomes less, the head of the humerus now projecting into it. When the folds are relaxed by bringing the arm to the side, the fingers can be pushed into the space so as to examine it.

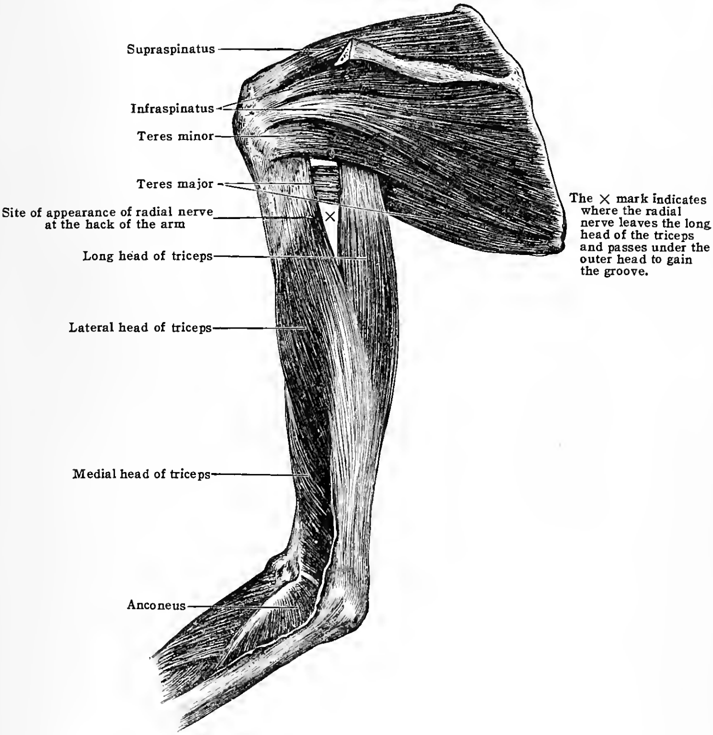
The axillary (circumflex) nerve and posterior circumflex vessels wind around the humerus under the deltoid; a line drawn at a right angle to the humerus and a little above the centre of this muscle marks their position on the surface.

To trace the **synovial membrane of the shoulder-joint** is a comparatively simple matter (fig. 1130). Covering both aspects of the free edge of the glenoid ligament, it lines the inner aspect of the capsule, whereby it reaches the articular margin of the head of the humerus; there is a distinct reflection, below, from the capsule on to the humeral neck before the rim of the cartilage is reached.

An extensive protrusion of synovial membrane takes place in the form of a synovial bursa, at the medial and anterior part of the capsule, near the root of the coracoid process under the tendon of the subscapularis. Another protrusion takes place between the two tuberosities along the intertubercular groove, as low as the insertion of the pectoralis major. A third synovial protrusion may be seen, but not frequently, at the lateral or posterior aspect, in the form of a bursa, under the infra-spinatus tendon. Thus the continuity of the capsule is interrupted by **two** and sometimes **three synovial protrusions.**

Shoulder-joint.—The frequency of **dislocations** here, nearly equal to those of all the other joints put together, calls attention to the points contributing to make the joint alike insecure and safe. **Strength** is given by (1) the intimate blending of the short scapular muscles, especially the subscapularis with the capsule; (2) the coraco-acromial vault; (3) atmospheric pressure; (4) the long tendon of the biceps; (5) the elasticity of the clavicle; (6) the mobility of the scapula. The **weakness of the joint** is readily explained by its free mobility, the want of correspondence between the articular surfaces, its exposure to injury, and the length of the humeral lever. The rent in the capsule is usually anterior and below, and to this spot the head of the humerus must be made to return. While dislocations are usually primarily subglenoid, owing to the above part of the capsule being the thinnest and least protected, they take usually a secondarily forward direction,

FIG. 1131.—POSTERIOR VIEW OF THE SCAPULAR MUSCLES AND TRICEPS.



as the triceps prevents the head passing backward. In addition to the above features of the lower part of the capsule, laxity is here also a marked feature, to allow of free abduction and elevation. This movement will be accordingly much checked by any inflammatory matting of this part of the capsule.

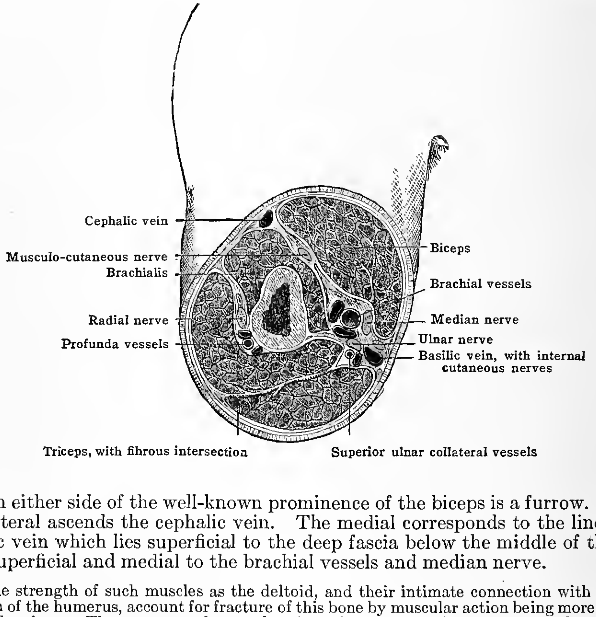
The **best incision for exploring the joint** is one commencing midway between the coracoid and acromion processes and carried downward parallel with the anterior fibres of the deltoid. The cephalic vein and biceps tendon are to be avoided. If drainage is needed, it must be supplied by a counter-incision behind. This may be made along the posterior border of the deltoid, part of its humeral attachment being detached if necessary. The axillary (circumflex) nerve must be avoided in the upper part of the incision.

The **shaft of the humerus** is well covered by muscles in the greater part of its extent, especially above. Below the insertion of the deltoid, the lateral border of the bone can be traced downward into the lateral supracondyloid ridge. The medial border and ridge are less prominent.

Attached to these ridges and borders are the intermuscular septa, each lying between the triceps and brachialis (anterior), and the lateral one giving origin to the brachio-radialis (supinator longus) and extensor carpi radialis longus as well. The medial extends up to the insertion of the coraco-brachialis, the lateral to that of the deltoid. The lateral septum is perforated by the anterior part of the profunda vessels and the radial (musculo-spiral) nerve, the medial by the superior and posterior branch of the inferior ulnar collateral (anastomotica magna) artery and the ulnar nerve.

The **biceps** has a two-fold attachment above and below. The former is of much importance in steadying the various movements, especially the upward one, and in harmonising the simultaneous flexion and extension of the shoulder- and elbow-joints. (Cleland.) The lacertus fibrosus curving downward and medially with its semilunar edge upward, across the termination of the brachial artery, strengthens the deep fascia and the origin of the flexors of the forearm. The two heads unite in the lower third of the arm. The tendon, before its insertion, becomes twisted, the lateral border becoming anterior.

FIG. 1132.—CROSS-SECTION THROUGH THE MIDDLE OF THE RIGHT ARM. (Heath.)



On either side of the well-known prominence of the biceps is a furrow. Along the lateral ascends the cephalic vein. The medial corresponds to the line of the basilic vein which lies superficial to the deep fascia below the middle of the arm, and superficial and medial to the brachial vessels and median nerve.

The strength of such muscles as the deltoid, and their intimate connection with the periosteum of the humerus, account for fracture of this bone by muscular action being more common than elsewhere. The presence of muscular tissue between the fragments, together with deficient immobilization, explains the fact that ununited fractures are also most common in the humerus. **The best incisions for exploring the humerus**, e. g., in acute necrosis, etc., are (*a*) for *the upper portion*, the two already mentioned along the anterior and posterior borders of the deltoid. In the latter case the presence of the radial (musculo-spiral) nerve in the deeper part of the wound must be remembered; (*b*) for *the lower end* one parallel with the lateral intermuscular septum, deepened between the brachialis and brachio-radialis.

A line drawn along the medial edge of the biceps from the insertion of the teres major to the middle of the bend of the elbow corresponds to the **brachial artery.** In the upper two-thirds, this artery can be compressed against the bone by pressure laterally; in its lower third the humerus is behind it, and pressure should be made backward. The presence of the median nerve will interfere with any prolonged digital pressure applied in the middle of the arm.

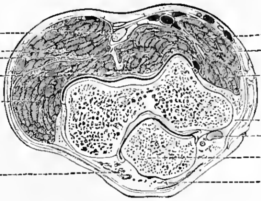
In ligature of the artery here the line extends from the mid-axillary region above, prolonged to the centre of the front of the elbow. The only structures seen should be the medial edge of the biceps, the basilic vein, and the median nerve. The profunda comes off 2.5 cm. (1 in.) below the teres major, having the same relation to the heads of the triceps; thus, it first lies on the long head, behind the axillary and brachial arteries, then between the long and medial heads, and next, in the groove, between the medial and lateral heads, and courses with the radial (musculo-spiral) nerve (fig. 1132); the nutrient artery arises opposite the middle of the humerus; in many cases it arises, on the back of the arm, from the profunda; the superior ulnar collateral (inferior profunda) below the middle, and courses with the ulnar nerve through the intermuscular septum to the back of the medial condyle. The inferior ulnar collateral (anastomotica magna) is given off from 2.5 to 5 cm. (1 to 2 in.) above the bend of the elbow. Fig. 1138 will show the **collateral circulation** after ligature of the brachial, according as the vessel is tied above or below the superior profunda, or below the superior ulnar collateral.

The **centre of the arm** is a landmark for many anatomical structures. On the lateral side is the insertion of the deltoid; on the medial, that of the coraco-brachialis. The basilic vein and the medial brachial cutaneous nerve (nerve of Wrisberg) here perforate the deep fascia, going in reverse directions. The superior ulnar collateral is here given off from the brachial and joins the ulnar nerve; the median nerve also crosses the artery, and the ulnar nerve leaves the medial side of the vessel to pass to the medial aspect of the limb.

The **brachialis** can be mapped out by two pointed processes which surround the insertion of the deltoid, pass downward into lines corresponding to the two intermuscular septa, and then converge over the front of the elbow to their insertion into the coronoid process.

The **median nerve** (lateral head, 5th. 6th, 7th C.; medial head, 8th C. and 1st T.) can be traced by a line drawn from the lateral side of the third part of the axillary and first part of the brachial artery, across this latter vessel about its centre, and then along its medial border to the forearm, where it passes between the two heads of the pronator teres.

Fig. 1133.—Cross-Section through the Elbow. (× 1/2). (After Braune.)



The **ulnar nerve** (8th C. and 1st T.) lies to the medial side of the above arteries as far as the middle of the arm, where it leaves the brachial to course more medially and perforate the medial intermuscular septum together with the superior and posterior branch of the inferior ulnar collateral and so get to the back of the medial condyle. A line drawn from the medial border of the coraco-brachialis, where, in the upper part of its course, the nerve is in close relation with the medial side of the axillary and brachial arteries, to the back of the medial condyle, will indicate its course. Low down, the nerve is in the medial head of the triceps, and may be injured in operations here.

The **radial (musculo-spiral) nerve** (5th, 6th, 7th, and 8th C.) can be traced by a line beginning behind the third part of the axillary artery, then carried vertically down behind the uppermost part of the brachial, and then, just below the posterior border of the axilla, curving backward behind the humerus and slightly downward just below the insertion of the deltoid. Thus, passing from laterally and from before backward in its groove, accompanied by the profunda vessels, first the trunk, and then the smaller anterior division, it again comes to the front by perforating the lateral intermuscular septum at a point about opposite to the junction of the middle and lower thirds of the arm, and passes down in front of the lateral supracondyloid ridge, lying here between the brachio-radialis and brachialis anterior, to the level of the lateral condyle, in front of which it divides into the superficial (radial) and deep (posterior interosseous) radials. The former of these accompanies the radial artery to the front of the arm, the latter travels backward to the back of the forearm. A line from the lateral condyle to the insertion of the deltoid indicates the lateral intermuscular septum.

In addition to injuries caused by fracture, the nerve may be injured in crutch pressure, the sleep of intoxication, use of an Esmarch's bandage, or the careless reduction of a dislocated shoulder with the foot in the axilla. To expose the nerve the incision begins below, over the lateral intermuscular septum, where it lies between the brachio-radialis and brachialis (anterior). Hence the incision is prolonged freely upward and backward toward the posterior border of the deltoid.

On the back of the arm is the **triceps muscle,** with its three heads and tendon of insertion, all brought into relief in a muscular subject when the forearm is strongly extended. Of the three heads, the medial is the least distinct, arising below the groove (musculo-spiral) for the radial (musculo-spiral) nerve, reaching to each intermuscular septum, and tapering away above as high as the teres major. Most of the fibres of this head lie deeply. The lateral head, arising above the groove as high as the great tuberosity, appears in strong relief just below the deltoid; while the middle or long head, arising from the scapula just below the glenoid cavity, appears between the teres muscles. The tendon of insertion, passing into the upper and back part of the olecranon over a deep bursa, is shown by a somewhat depressed area. On the lateral side, an important expansion to the fascia over the anconeus is given off.

Fig. 1134.—The Elbow-Joint, as Shown by the Röntgen-rays.

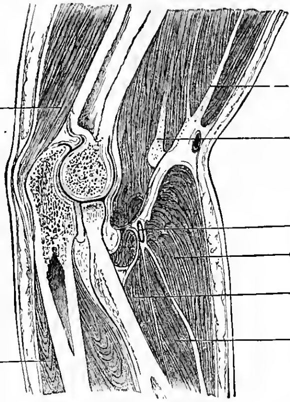
In the ossification of the humerus the epiphyses are of first importance. The **upper,** consisting of those for the head and two tuberosities, which form one about the seventh year, blends with the shaft between the twentieth and twenty-fifth years. Separation usually takes place at an earlier date, this being explained by the fact that the cone-like arrangement by which the diaphysis fits into the cap of the epiphysis becomes more marked toward the date of union, and thus tends to prevent displacement. (Thomson.) The **lower epiphysis.** The condition of this varies with the degree of coalescence of its four centres. The first and chief, that for the capitulum (second or third year), unites with those for the trochlea and lateral epicondyle soon after puberty, and forms an epiphysis which joins with the shaft at about sixteen. The epiphysis for the medial epicondyle appears at the fifth year and unites with the shaft at the eighteenth. Injury to this epiphysis may damage the ulnar nerve and open the elbow-joint. Thus, at and after puberty, there are two chief epiphyses to remember here:—(*a*) the larger, consisting of capitular, trochlear, and lateral epicondyle centres. This is almost entirely intra-articular; (*b*) the smaller, that for the medial epicondyle; the extent to which this is intra-articular varies. The structures that would be divided in **an amputation at the centre of the arm**

are shown in fig. 1132. The chief points needing attention are:—(1) To leave as much of the lever of the humerus as possible; (2) clean section of the large nerves, the radial (musculospiral) in its groove being especially liable to be frayed by the saw; (3) the difference between the amount of retraction of the free biceps in front, and the triceps behind, fixed to the bone and septa.

THE ELBOW

The **bony points**, epicondyles, olecranon, and head of radius, andtheir relation to one another, should be carefully studied. The *medial epicondyle* is the more prominent of the two, is directed backward as well as medially, and lies a little above its fellow. Above it can be traced upward the supracondyloid ridge and corresponding intermuscular septum. The *lateral epicondyle* is more rounded, and thus less prominent; below, and a little behind it, the *head of the radius* can be felt moving under the capitulum when the forearm is supinated and flexed. A depression marks this spot and corresponds to the interval between the anconeus and brachio-radialis and extensor carpi radialis longus; at the back, the upper part of the *olecranon* is covered by the triceps. The lower part is subcutaneous, and separated from the skin by a bursa. If the thumb and second finger be placed on the epicondyles and the index on the tip of the olecranon, and the forearm completely extended, the tip of the olecranon rises so as to be on the line joining the two epicondyles. In flexion at a right angle, the olecranon is below the line of the

Fig. 1135.—Longitudinal Section of the Elbow-joint. (One-half.) (Braune.)

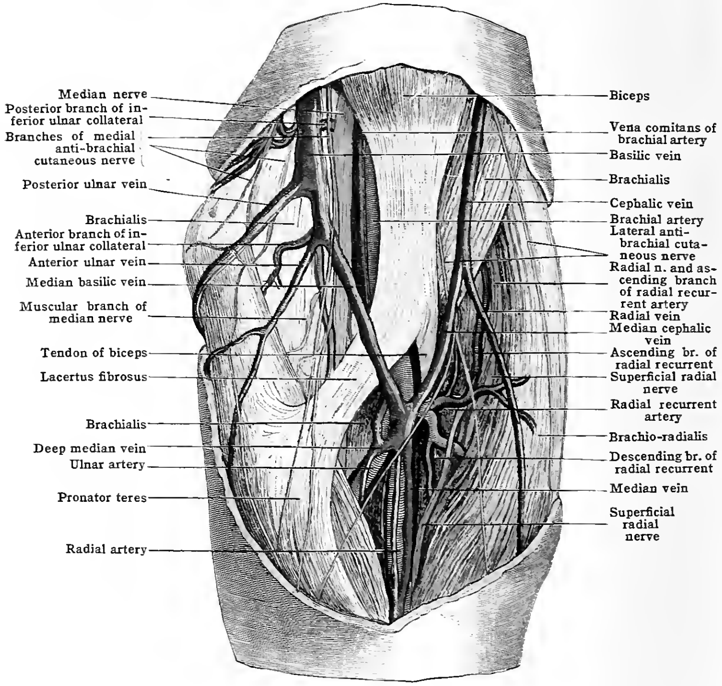


epicondyles, and in complete flexion quite in front of them. Between the medial epicondyle and olecranon is a pit, in which lie the ulnar nerve and the anastomosis between the inferior ulnar collateral and the posterior ulnar recurrent arteries. The coronoid process is so well covered by muscles, vessels, and nerves that its position cannot be distinctly made out.

The synovial membrane of the elbow-joint communicates with that of the superior radio-ulnar. Hence the facility with which tuberculous disease may be set up after neglected falls on the hand, in early life. At this time the weakness of the annular (orbicular) ligament leads to its being easily injured. Swelling, due to effusion into the joint, appears on either side of the triceps tendon, and soon obliterates the depression below the lateral epicondyle. The simplest incision for an infected elbow-joint is a vertical one, on the lateral side of the olecranon. A superficial swelling over the tip of the olecranon is due to effusion into the bursa between the soft parts and that bone. A deeper, less easily defined swelling in the same region is due to inflammation of the bursa between the olecranon and the triceps. A swelling on the medial side of the elbow-joint, if painful and accompanied by inflammation of the skin, may be due to mischief in the **epitrochlear lymphatic node** situated just above the medial epicondyle, and receiving lymphatics from the medial border of the forearm and the two medial fingers.

The hollow in front of the elbow.—The delicacy of the skin here must always be borne in mind in the application of splints. Owing to the insidious rapidity with which pressure may set up ischæmic paralysis, anterior angular splints are always to be used with caution. The **M**-like arrangement of the superficial veins as usually described is by no means constant (fig. 1136). The median basilic is the vein usually chosen for venesection, owing to its larger size and its being firmly supported by the subjacent bicipital fascia which separates it from the brachial artery; but the median cephalic is the safer. The median basilic is crossed by branches of the medial antibrachial (internal) cutaneous nerve, while those of the musculo-cutaneous lie under the median cephalic. In the semiflexed position, the fold of the elbow is seen, a little above the level of the joint. This forms the base of the *triangular fossa* below the elbow, the lateral side corresponding to the brachio-radialis, the medial to the pronator teres, and the apex to the meeting of these muscles. The tendon of the biceps can be easily made out in the centre of the fossa, giving off above the lacertus fibrosus from its medial side to fasten down the flexors of the forearm. Under the tendon on its medial side lie the brachial artery and the median nerve, a little medial to it, for a short distance. The radial nerve (musculo-spiral) lies outside the fossa, between the brachio-radialis and the brachialis (anterior), and gives off its two

FIG. 1136.—THE BEND OF THE ELBOW WITH THE SUPERFICIAL VEINS.
(From a dissection by Dr. ALDER SMITH in the Museum of St. Bartholomew's Hospital.)



terminal branches in front of the lateral epicondyle. The brachial usually bifurcates opposite to the neck of the radius.

The **arterial anastomoses about the elbow-joint** are as follows: The radial recurrent runs up under cover of the brachio-radialis to anastomose with the anterior branch of the profunda **on the front of the lateral condyle.** The posterior interosseous recurrent ascends, between the supinator and the anconeus, to anastomose **on the back of the lateral condyle** with the posterior branch of the profunda. It further joins, by a large anastomotic arch across the back of the joint, with the inferior ulnar collateral (anastomotic magna) and posterior ulnar recurrent. The anterior ulnar recurrent passes upward on the brachialis to join the anterior **part of the** inferior ulnar collateral under the pronator teres, on the front of the medial epicondyle. The posterior ulnar recurrent makes for the interval between the **back of the medial epicondyle** and the olecranon, to join with the superior and the posterior branch of the inferior ulnar collateral.

It will be seen that the inferior ulnar collateral (anastomotica magna) is the artery most largely employed, distributing branches everywhere, save to the front of the lateral epicondyle.

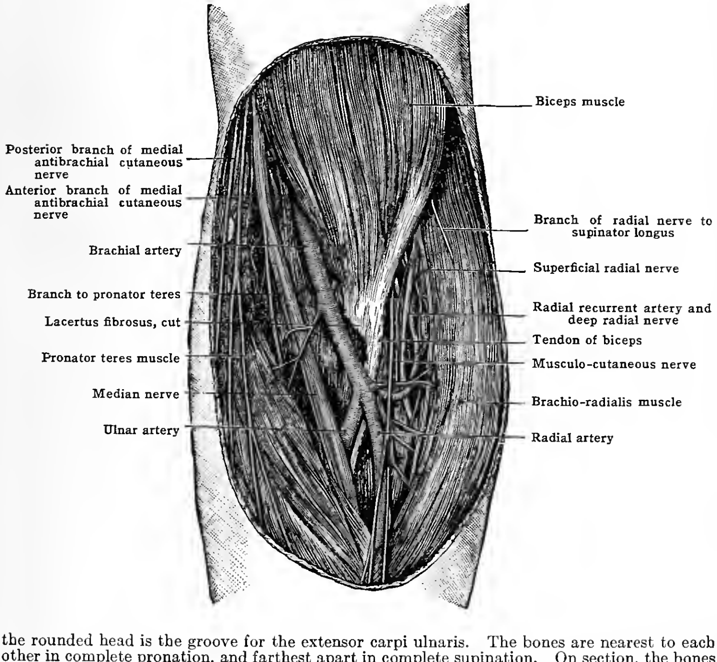
THE FOREARM

Bony landmarks.—The *posterior border of the ulna* can be easily traced down from the olecranon to the back of the styloid process; the bone becomes somewhat rounded below, and lies between the flexor and extensor carpi ulnaris. The tip of the *styloid process* corresponds to the medial end of the line of the wrist-joint. The *radius* is covered above by the brachio-radialis and radial extensors of the carpus, and the outline of the bone is less easily followed. Its *styloid process* is readily made out below a finger's breadth above the thenar eminence. It is placed about 1.2 cm. ($\frac{1}{2}$ in.) lower than that of the styloid process of the ulna.

Thus, a line drawn straight between the two processes would fall a little below that of the wrist-joint, this being shown by a line drawn between the two processes forming a slight curve, with its concavity downward (corresponding to the concavity of the lower surface of the radius and fibro-cartilage) about 1.2 cm. ($\frac{1}{2}$ in.) above the straight line given above.

The radial styloid process is covered by the abductor longus and extensor brevis pollicis, while farther out lies the extensor pollicis longus. Between the styloid process of the ulna and

FIG. 1137.—THE BRACHIAL ARTERY AT THE BEND OF THE ELBOW.
(From a mounted specimen in the Anatomical Department of Trinity College, Dublin.)

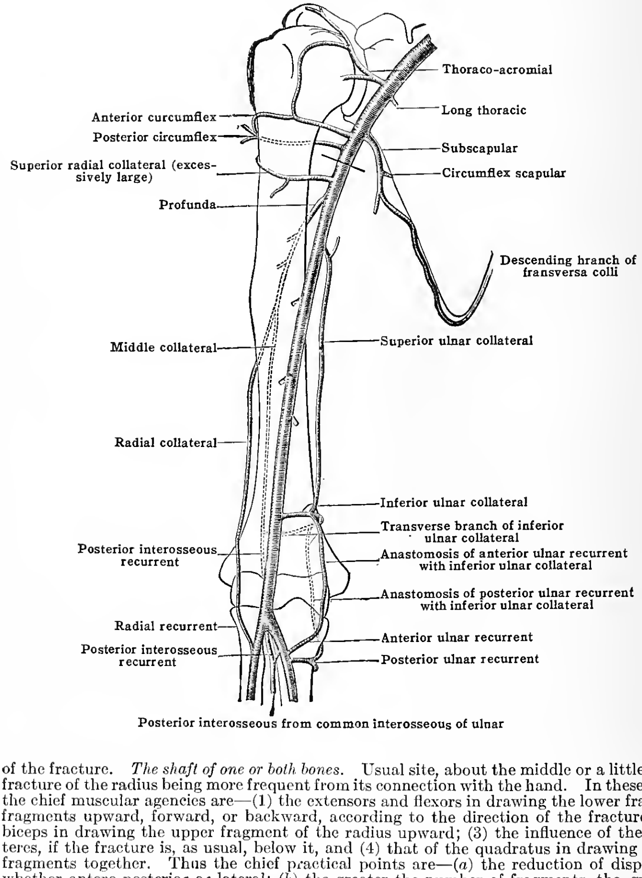


the rounded head is the groove for the extensor carpi ulnaris. The bones are nearest to each other in complete pronation, and farthest apart in complete supination. On section, the bones are found at every point nearer to the back than to the front of the limb, but increasingly so above. 'The lower the section proceeds down the limb, the less will the bones be covered at the sides, and the more equally will the soft parts be distributed about the anterior and posterior aspects of the limb. It will be noticed that where one bone is the more substantial, the other is the more slender, as near the elbow and wrist; and that it is about the centre of the limb that the two are most nearly of equal strength.' (Treves.) When the limb is pronated, the interosseous space is narrowed; in supination and the mid-position it is widened out. In pronation, both styloid processes can be distinctly made out; in supination, that of the radius is the more distinct, as now the skin and soft parts are stretched and raised over that of the ulna.

Joints.—The position of the **superior radio-ulnar joint** is marked by a dimple about 12 mm. ($\frac{1}{2}$ in.) below the lateral epicondyle. The **inferior** can just be felt, when the forearm is pronated, between the head of the ulna and lower end of the radius. The recessus sacciformis here may be enlarged in rheumatic and other affections. The **interosseous membrane** not only ties the bones together and gives attachment to muscles, but in falls on the hand it enables the ulna to participate in the shock.

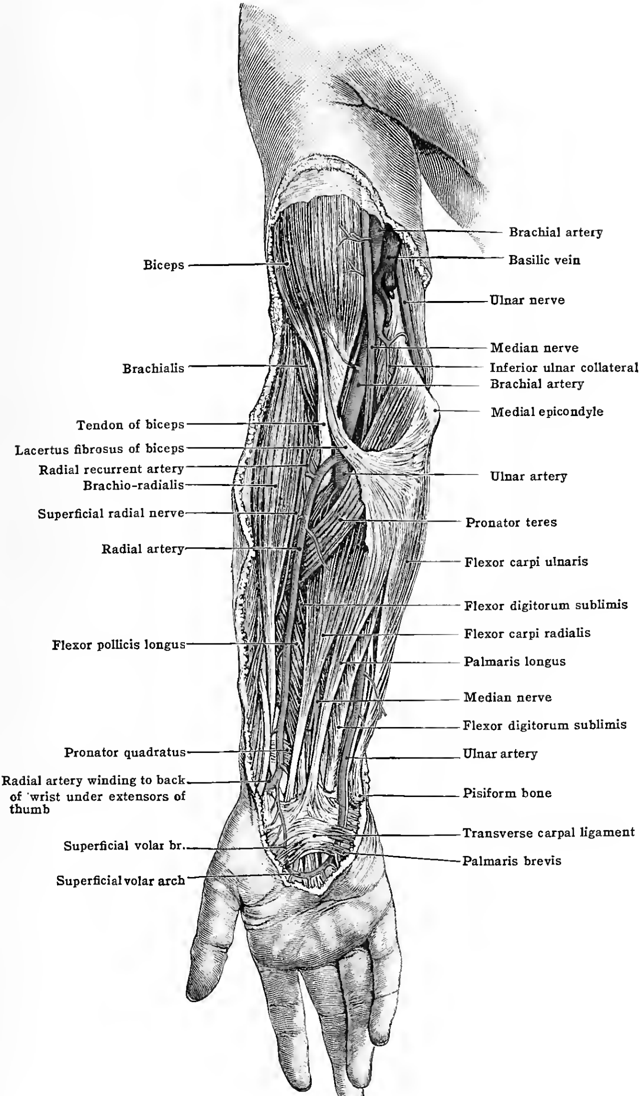
The following are important points with regard to **the bones**. *Common fractures. Olecranon.*—This usually takes place at the constricted centre of the semilunar (greater sigmoid) notch or the junction of the olecranon with the shaft. A fall is here the usual cause, and the heavier the fall, the more frequently is the fracture nearer the shaft, though displacement is now likely to be slight, owing to the abundance of fibrous and muscular structures on both sides

FIG 1138.—DIAGRAM OF THE ANASTOMOSES OF THE BRACHIAL ARTERY. (MacCormac and Anderson.)



of the fracture. *The shaft of one or both bones.* Usual site, about the middle or a little below it, fracture of the radius being more frequent from its connection with the hand. In these fractures the chief muscular agencies are—(1) the extensors and flexors in drawing the lower fragment or fragments upward, forward, or backward, according to the direction of the fracture; (2) the biceps in drawing the upper fragment of the radius upward; (3) the influence of the pronator teres, if the fracture is, as usual, below it, and (4) that of the quadratus in drawing the lower fragments together. Thus the chief practical points are—(*a*) the reduction of displacement, whether antero-posterior or lateral; (*b*) the greater the number of fragments, the greater the tendency to union across the interosseous space, with its embarrassing results, and the greater the need of a supinated position in the setting; (*c*) the risk of gangrene here from the facility with which the vessels are compressed against the contiguous bones, especially in flexion of the forearm; and the consequent need of attention to the width of the splints and the bandaging; (*d*) the readiness with which ischæmic paralysis may rapidly and insidiously be caused. **Colles' fracture.** Here, after a fall on the hand, the radius gives way usually at its weakest part, about

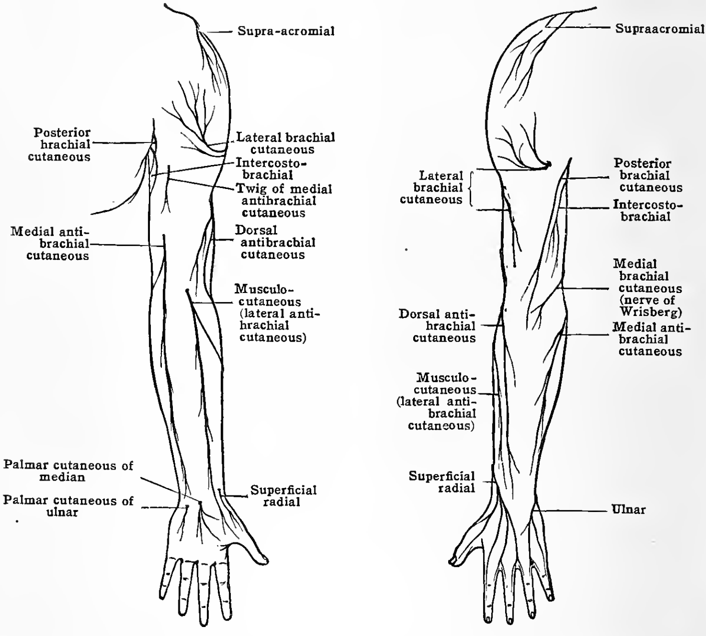
FIG. 1139.—THE ARTERIES OF THE FOREARM WITH THE SUPERFICIAL VOLAR ARCH.



18 mm. ($\frac{3}{4}$ in.) above its extremity, where the narrow compact tissue is suddenly expanding into cancellous. There is frequently impaction of the upper into the lower fragment. There is a three-fold displacement of the lower fragment:—(1) It is driven and drawn upward and backward. (2) It is rotated so that its articular surface looks somewhat backward. (3) It is drawn to the radial side. The chief causes of the discreditable stiffness often allowed to result are non-reduction of the deformity, adhesions in the opened wrist-joint, teno-synovitis, and prolonged immobilisation.

Separation of epiphysis.—This may take place in the **radius** up to about the age of eighteen: it is commoner before. Its possible importance in interfering with the symmetry of the growth of the bones is obvious. Here, as in Colles' fracture, the level of the styloid processes of the radius and ulna, and the correspondence of the two styloid processes of the radii, are important in diagnosis. **Exposure of the bones.** In the case of ununited fracture or necrosis the **radius** may be reached—(*a*) *Behind*, by an incision in a line drawn from the lateral epicondyle to the back of the radius. The field opened here lies between the brachio-radialis and the radial extensors on the one side, and the common extensor on the other. Care must be taken of the

Fig. 1140.—Distribution of Cutaneous Nerves on the Anterior and Posterior Aspects of the Superior Extremity.



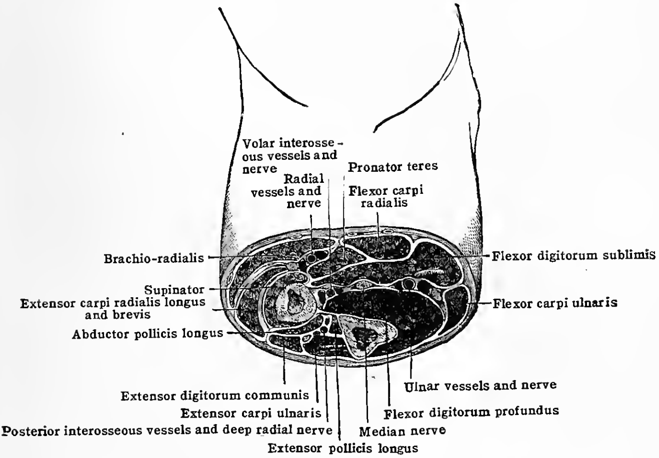
deep radial (posterior interosseous) nerve. (*b*) *In front.* The incision here lies in the sulcus between the brachio-radialis and the flexors. The pronator teres and the flexor sublimis must, in part, be detached from the radius. If more room is required to reach an injured upper extremity of the radius, the incision will descend from above the lateral epicondyle in the groove between the anconeus and common extensors. In the detachment of the supinator the deep radial nerve will again need attention. The **ulna** is more easily reached by an incision between the flexor and extensor carpi ulnaris. In removal of the lower part of the bones for myeloid sarcoma or osteitis, the ulna is reached in the interval last mentioned. The radius is best exposed by an incision between the brachio-radialis and extensor carpi radialis longus, the superficial radial nerve being the guide. (Morris.) Finally, the so-called 'carrying angle' of the forearm deserves mention. In extension the bones of the forearm are not in a straight line with the humerus, but directed slightly laterally, the angle at the elbow-joint being obtuse, and open laterally. This angle is so named from its facilitating carrying objects during walking. In flexion the forearm is deflected somewhat toward the middle line, mouth, etc. These properties are liable to be lost under many and widely different conditions, of which injuries to the epiphyses of the humerus, badly united fractures of the forearm, and osteoarthritis of the elbow-joint are instances.

Soft parts.—Along the lateral border, of the forearm descend the brachioradialis and radial extensors of the carpus, fleshy above, tendinous below. About 3.7 cm. ($1\frac{1}{2}$ in.) above the styloid process of the radius, a fleshy swelling directed obliquely downward and forward from behind, across this lateral border of the forearm, denotes the extensors of the thumb crossing those of the carpus.

Along the medial border is the fleshy mass of the pronator teres and flexors, the ulna being covered by the flexor carpi ulnaris and flexor profundus. The tendon of the pronator is inserted into the radius a little below its centre—a point of importance in the treatment of fractures and in amputation. The flexor carpi ulnaris tendon can be felt just above the wrist making for the pisiform bone; and just lateral to it lies the **ulnar artery,** about to pass over the transverse carpal (anterior annular) ligament.

The course of the artery is denoted by the lower two-thirds of a line drawn from the front of the medial epicondyle to the lateral edge of the pisiform bone. From the bifurcation of the brachial, a line drawn to meet the former at the junction of its middle and upper third marks the upper part of the artery, here thickly covered by muscles. **In ligature of the artery** in *the middle* of the forearm, the white line and sulcus between the flexor carpi ulnaris and sublimis must be identified. A small muscular branch will often lead down to the artery. The line of the **ulnar nerve** is one drawn from the interval between the medial epicondyle and the

FIG. 1141.—SECTION THROUGH THE MIDDLE OF THE RIGHT FOREARM. (Heath.)



olecranon to the medial side of the ulnar artery just above the wrist. The nerve joins the artery at the junction of the upper and middle thirds of the forearm. The **median nerve** runs in a line drawn from the medial side of the brachial artery, in the elbow triangle, to a point beneath, or just to the medial side of, the palmaris longus at the mid-point of the front of the wrist. The **radial artery** will be marked by a line drawn from the centre of the bend of the elbow (where the brachial artery divides opposite to the neck of the radius) to a point just medial to the radial styloid process descending along the medial edge of the brachio-radialis. The muscular interval is that between the brachio-radialis and pronator teres above, and the flexor carpi radialis below. The **superficial radial nerve** will be marked by the same line (it lies just lateral to the artery) for its upper two-thirds; it then leaves the artery about 7.5 cm. (3 in.) above the wrist-joint, and passes to the back of the forearm under the tendon of the brachio-radialis. The **volar interosseous artery** runs down on the interosseous membrane and passes to the back of the forearm by perforating it below, having passed behind the pronator quadratus. The **dorsal interosseous** lies between the superficial and deep extensors. These small arteries reinforce the palmar through the carpal arches, and thus bring down blood after ligature of the trunks above.

The front of the forearm is supplied by the *musculo-cutaneous* on the lateral, and the *medial antibrachial* (internal) cutaneous on the medial, side; just above the wrist the palmar cutaneous branches of the median and ulnar perforate the deep fascia (fig. 1140). The back of the forearm is supplied by the *radial* (musculo-spiral) and posterior branches of the musculo-cutaneous laterally, and the posterior branches of the medial antibrachial cutaneous medially (fig. 1140).

The **lymphatics of the upper extremity** are **superficial** and **deep;** the former run with the superficial veins, the latter with the deep vessels. Occasionally a few small **nodes** occur below the elbow. The epitrochlear nodes lie upon the basilic vein, a little above the medial epicondyle and draining the fourth and fifth digits. The majority of the lymphatics open into the axillary nodes, and terminate, on the left side in the thoracic duct, on the right in the lymphatic duct. A few, accompanying the cephalic vein, reach the subclavian or infraclavicular nodes, and thus communicate with the lymphatics of the neck.

It will be well briefly to consider here the chief *results of paralysis* of the main nerves of the upper extremity.

Paralysis of the median nerve.—(*a*) *In forearm:* Loss of pronation. (*b*) *At wrist:* Diminished flexion and tendency toward ulnar adduction. (*c*) *In the hand:* Power of grasp is lessened especially in the thumb and lateral two fingers. Owing to the loss of flexion in the phalanges of these fingers the phalanges are liable to become overextended by the action of the extensors and interossei. The thumb remains extended, adducted, and closely applied to the index, the human characteristic being thus lost, and the 'ape's hand' of Duchenne being produced. **Sensation** will be lost over the palmar aspect of the thumb and lateral two and one-half fingers and over the distal ends of the same fingers, to a varying degree, according to the sensory distribution of the median and other cutaneous nerves. The above applies to lesions of the trunk. If the nerve be injured at the wrist, flexion of the wrist and fingers is less interfered with.

Paralysis of the ulnar nerve.—(*a*) *At wrist:* Power of flexion is diminished and that of ulnar adduction lost. (*b*) *In the hand:* Power of grasp will be lessened in the ring and little fingers. The interossei will be powerless to abduct or adduct the fingers, and there will be marked wasting of the interosseous spaces and hypothenar eminence. The thumb cannot be adducted. After a time, from paralysis of the lumbricals and interossei, the hand becomes 'clawed'—the first phalanges overextended, and the second and third flexed (**main en griffe**). Sensation will be lessened over the area supplied by the nerve.

Paralysis of the radial (musculo-spiral) nerve.—(*a*) *In the forearm* This is flexed, extension being impossible. The forearm is pronated, supination being impossible save by biceps, which acts now most strongly on a flexed elbow-joint. (*b*) *In the wrist:* This is dropped, owing to the loss of extension. (*c*) *In the hand:* The thumb is flexed and adducted. Some slight power of extension of the second and third phalanges of the fingers remains by means of the lumbricales and interossei. **Sensation** is impaired over the posterior and lateral aspect of the forearm and lost to a varying extent over the distribution of the radial on the back of the hand.

Paralysis of the deep radial (posterior interosseous) nerve.—The evidence here is somewhat similar to that just given, but with the following differences. (*a*) *In the forearm:* There is no loss of extension, and the loss of supination is less as the brachio-radialis is not paralysed. (*b*) *At the wrist:* The 'drop' and loss of extension are not so marked, as the extensor carpi radialis longus escapes. **Sensation:** There is no loss.

Paralysis of the musculo-cutaneous nerve.—*Forearm:* Power of flexion is impaired, owing to complete paralysis of the biceps and partial of the brachialis (anterior). **Sensation:** This is impaired over the lateral aspect of the forearm, both back and front.

Amputation of forearm.—The 'mixed' method by skin-flaps roundly arched and circular division of the soft parts, the dorsal flap being the longer, is the most generally applicable. The bones should always be sawn below the pronator teres, when possible. In sawing them they must be kept parallel, the limb being in the supinated position. As the radius is the less securely held above, it is well to complete the section of this bone first. The relative position of the vessels has been indicated above (p. 1423, and figs. 1139 and 1141).

THE WRIST AND HAND

Bony points.—On the medial side the *styloid process* and, further laterally, the *head of the ulna* can be made out. On the lateral side, the *radial styloid process* descends about 1.2 cm. ($\frac{1}{2}$ in.) lower than that of the radius, and is somewhat anterior to it. Abduction of the hand is thus less free than adduction. Between the apex of the styloid process and the ball of the thumb a bony ridge can be felt, with some difficulty, formed by the *tubercle of the navicular* and the ridge of the *greater multangular* (trapezium). At the base of the hypothenar eminence the *pisiform* can be more readily distinguished. The *hook of the hamatum* (unciform) lies below and to the radial side of the pisiform. On the front of the metacarpo-phalangeal joint of the thumb, the *sesamoid bones* can be distinguished.

At the back of the wrist and hand the *triquetrum* (cuneiform) bone can be felt below the head of the ulna; and more toward the middle line the prominence of the *capitatum* (os magnum), which supports the third or longest digit.

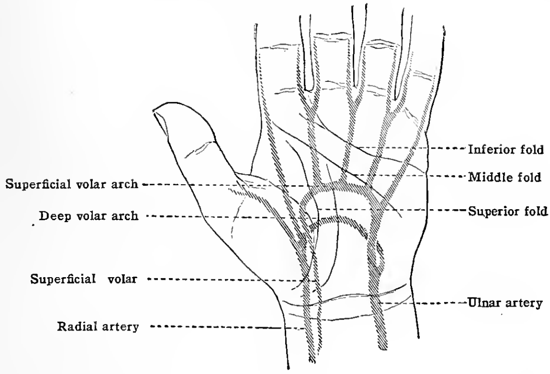
A line drawn from the base of the fifth metacarpal bone to the radio-carpal joint, slightly curved downward, will give the line of the carpo-metacarpal joints. (Windle.) When the fingers are flexed, it will be seen that in each case it is the proximal bone which forms the prominence; thus, the knuckle is formed by the head of the metacarpal, the interphalangeal prominence by the head of the first phalanx, and the distal one by the head of the second. Thus, the joint in each case lies below the prominence, the distal joint being 2 mm. ($\frac{1}{12}$ in.), the interphalangeal 4 mm. ($\frac{1}{6}$ in.), and the metacarpo-phalangeal 8 mm. ($\frac{1}{3}$ in.) below its prominence.

Skin and skin-folds.—The *skin* over the palm is thickened over the heads of the metacarpal bones and hypothenar eminence, thinner over the thenar. It is peculiar in its absence of sebaceous glands and hair-follicles; hence the absence of boils and sebaceous cysts. It is intimately connected with the palmar fascia, hence the chief difficulty in operations when this is contracted. Over the pulp of the digits the skin is closely connected with the periosteum of each ungual phalanx. The importance of this is alluded to under the heading of whitlow (*vide infra*).

Skin-folds: two or three of these are seen on the palmar surface of the wrist: two lower down, and usually close together, and one less well marked, a little higher up upon the forearm. None of these corresponds exactly to the wrist-joint (fig. 1142). The lowest 'precisely crosses the arch of the os magnum in the line of the third metacarpal bone' (Tillaux), and is not quite 1.8 cm. ($\frac{3}{4}$ in.) below the arch of the wrist-joint. It is about 1.2 cm. ($\frac{1}{2}$ in.) above the carpo-metacarpal joint line, and indicates very fairly the upper border of the transverse carpal (anterior annular) ligament.

'Of the many creases in the skin of the palm, three require especial notice. The first starts at the wrist, between the thenar and hypothenar eminences, and, marking off the former emi-

FIG. 1142.—RELATION OF THE VOLAR ARCHES TO THE FOLDS OF THE PALM. (Modified from Tillaux.)

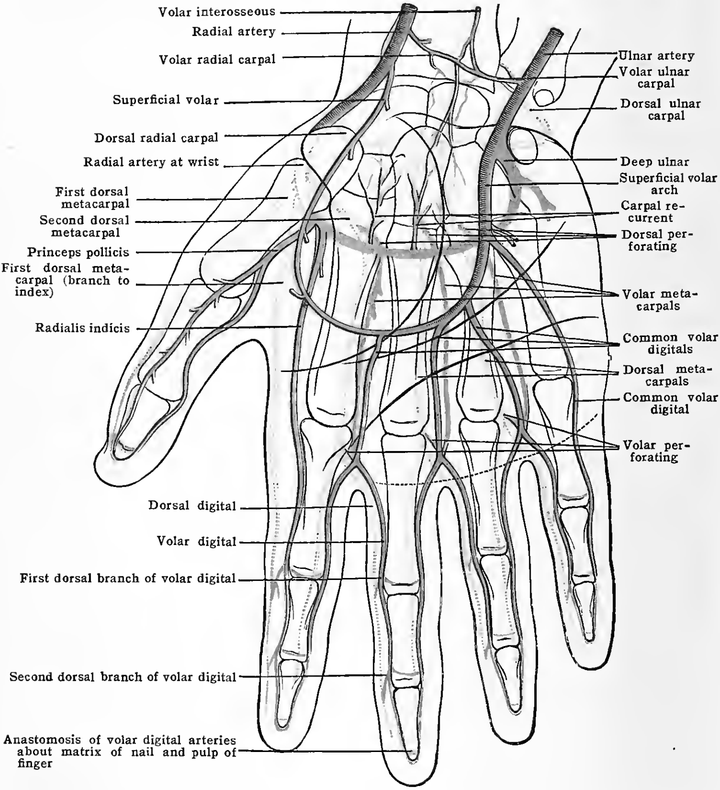


nence from the palm, ends at the lateral border of the hand and at the base of the index-finger. The second fold is slightly marked. It starts from the lateral border of the hand, where the first fold ends. It runs obliquely medially across the palm, with a marked inclination toward the wrist, and ends at the lateral limit of the hypothenar eminence. The third, lowest, and best marked of the folds starts from the little elevation opposite the cleft between the index and middle fingers, and runs nearly transversely to the ulnar border of the hand, crossing the hypothenar eminence at the upper end of its lower fourth. The first fold is produced by the adduction of the thumb; the second, mainly by the bending simultaneously of the metacarpo-phalangeal joints of the first and second fingers; and the third by the flexion of the three medial fingers. The second fold, as it crosses the third metacarpal bone, about corresponds to the lowest part of the superficial volar arch. The third fold crosses the necks of the metacarpal bones, and indicates pretty nearly the upper limits of the synovial sheaths for the flexor tendons of the three lateral fingers. A little way below this fold, the palmar aponeurosis breaks up into its four slips, and midway between the fold and the webs of the fingers lie the metacarpo-phalangeal joints. Of the transverse folds across the fronts of the fingers, corresponding to the metacarpo-phalangeal and interphalangeal joints, the highest is placed nearly 18 mm. ($\frac{3}{4}$ in.) below its corresponding joint. The middle folds are multiple for all the fingers, and are exactly opposite to the first interphalangeal joints. The distal creases are single, and are placed a little above the corresponding joints. There are two single creases on the thumb corresponding to the two joints, the higher crossing the metacarpo-phalangeal joint obliquely. The free edge of the web of the fingers, measured from the palmar surface, is about 1.8 cm. ($\frac{3}{4}$ in.) from the metacarpo-phalangeal joints. (Treves.)

The **superficial volar arch,** formed by the ulnar anastomosing with the superficial volar, or radialis indicis, will be shown by a line descending to the radial side of the pisiform bone, and then, a little lower, curving across the palm on a line with the thumb when outstretched at right angles with the index-finger. The four common digital arteries, the main branches of the superficial arch, run downward along the interosseous spaces, and bifurcate 12 mm. ($\frac{1}{2}$ in.) above the webs of the fingers; the most medial digital does not bifurcate.

The digital arteries then descend along the sides of the fingers under the digital nerves, giving off twigs to the sheath of the tendons, which enter by apertures in it, and run in the vincula vasculosa. It is owing to the readiness with which these tiny twigs are strangled by inflammation that sloughing of the tendon takes place so readily and irreparably. Throughout its course the superficial volar arch deserves its name. It is only covered by the palmaris

Fig. 1143.—Anastomoses and Distribution of the Arteries of the Hand.

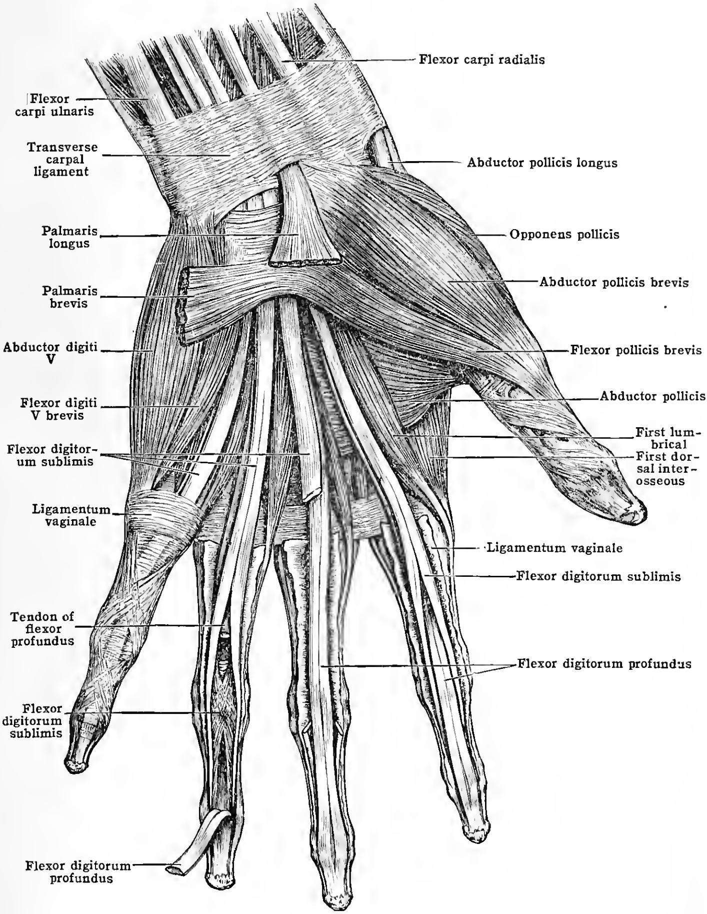


brevis and central part of the palmar fascia. Beneath it, medio-laterally are the flexor brevis and opponens digiti quinti, the digital branches of the ulnar and median nerves, and the flexor tendons and lumbricales.

The **deep volar arch,** formed by the radial and communicating branch of the ulnar, lies about 1.2 cm. ($\frac{1}{2}$ in.) nearer to the wrist than the superficial. It is not so curved as the superficial arch, and rests upon the interossei and metacarpal bones just below their bases. The structures separating it from the superficial arch have been already given.

Owing to the frequency of wounds here, the relation of *the structures in front of the wrist* is most important. The radial artery lies between the tendon of the brachio-radialis and flexor carpi radialis. Next to this tendon is the palmaris longus, when present. At the mid-point of the front of the wrist and usually under the palmaris longus is the median nerve. To the medial side of the palmaris longus is the flexor sublimis, the tendons for the middle and ring-finger being in front. The tendon of the flexor carpi ulnaris is most medial and between this and the superficial flexor of the finger the ulnar nerve and vessels have come up into a superficial position.

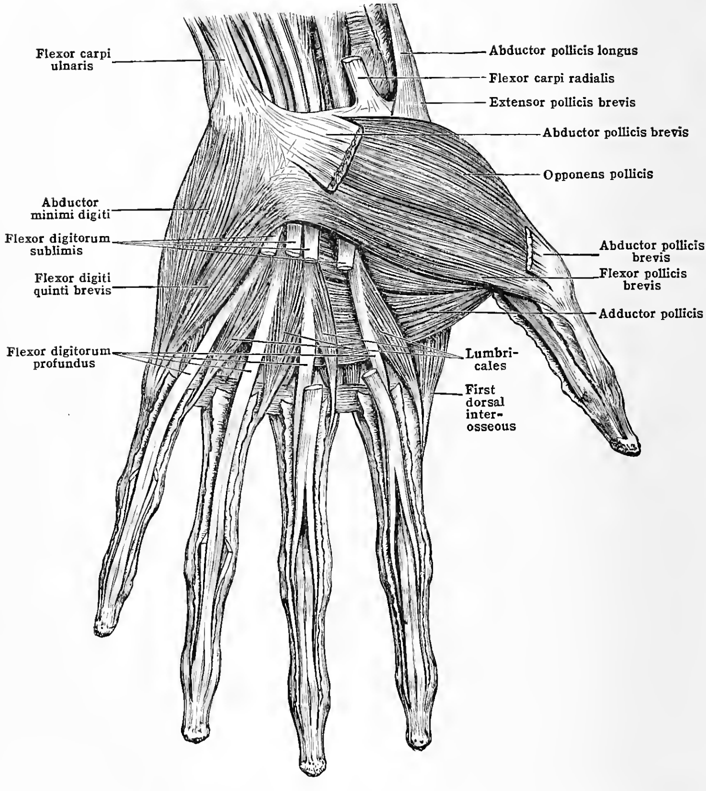
Fig. 1144.—The Superficial Muscles of the Palm of the Hand.



Fasciæ and sheaths.—The **transverse** and **dorsal carpal** (annular) **ligaments** bind down and hold in place the numerous tendons about the wrist. The **transverse carpal** (anterior annular), when healthy, cannot be detected. It is attached to the pisiform and triquetral (cuneiform) bones on the medial, and to the navicular and greater multangular (trapezium) on the lateral, side.

The ulnar nerve and vessels, the superficial volar, and palmar cutaneous branches of the median and ulnar pass over it. The ulnar artery and nerve are especially protected by their position between the pisiform and hook of the hamate (unciform), and also by a process of the flexor carpi ulnaris, which passes to the transverse ligament, thus forming a kind of tunnel. The flexor carpi radialis passes through a separate sheath formed by the ligaments and the groove in the greater multangular; while beneath the ligaments lie the flexor tendons, the median nerve, and accompanying artery. Attached to its upper border is the deep fascia of the forearm, and to its lower the palmar fascia and the palmaris longus tendon, while from the lateral and medial parts arise some of the thenar and hypothenar muscles. The upper border of the transverse carpal ligament corresponds to the lower of the two lines which

Fig. 1145.—The Deeper Muscles of the Palm of the Hand.



cross the wrist just above the thenar and hypothenar eminences. The large synovial sheath, for all the flexors of the fingers, reaches beneath and below the transverse ligaments as far as the middle of the palm, and above the wrist for 3.7 to 5 cm. ($1\frac{1}{2}$ to 2 in.).

The **dorsal carpal** (posterior annular) **ligament** is attached to the back of the lateral margin of the radius above the styloid process, and medially to the back of the styloid process of the ulna, the triquetrum and pisiform. Its direction is oblique, being higher on the radial side. It contains six tendon-compartments, of which four are on the radius.

The most lateral contains the long abductor and short extensor of the thumb; the second the two radial extensors of the carpus; the third, the extensor pollicis longus; this deep and narrow groove can be identified when the hand is extended, by its prominent lateral margin; the fourth transmits the extensor communis and extensor indicis proprius; the fifth, lying between the

FIG. 1146.—SECTION THROUGH REGION OF WRIST, A LITTLE ABOVE THE JOINT. RIGHT SIDE, UPPER HALF OF THE SECTION. (Tillaux.)

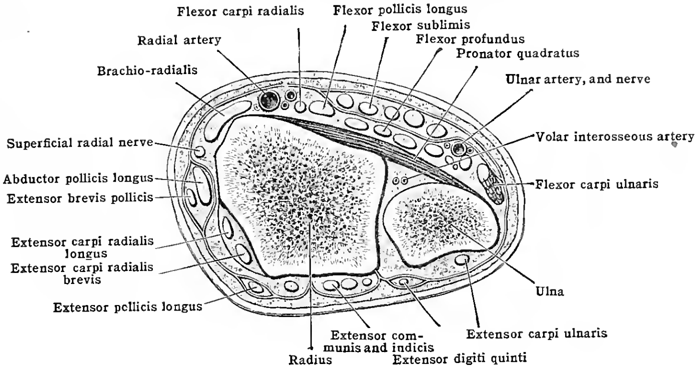


FIG. 1147.—REGION OF THE WRIST, AS SHOWN BY THE RÖNTGEN-RAYS.

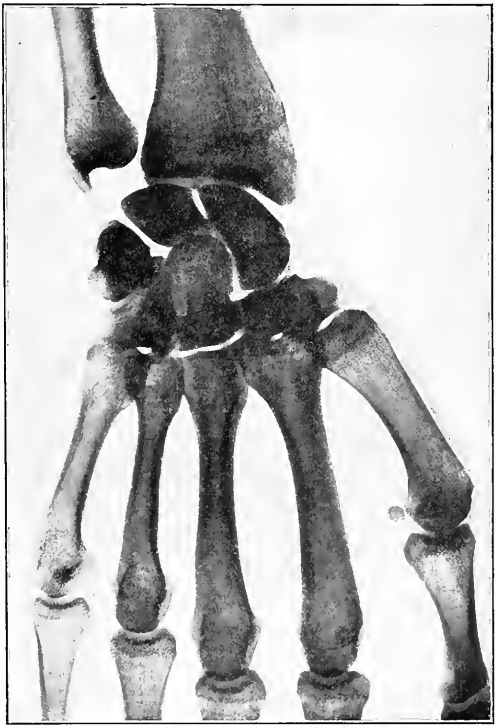

radius and ulna, the extensor digiti quinti; and the sixth, lying just lateral to the styloid process of the ulna, the extensor carpi ulnaris. The sheaths for the last two extensors are the only ones which follow the tendons of their insertion, the others ending at a varying distance below the carpal ligament. The lower border of the dorsal carpal corresponds to the upper margin of the transverse carpal ligament.

FIG. 1148.—TRANSVERSE SECTION OF THE WRIST THROUGH THE MIDDLE OF THE PISIFORM BONE.

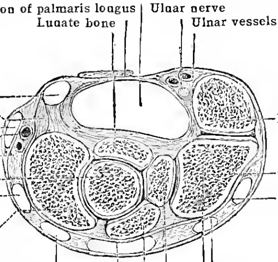

FIG. 1149.—DIAGRAM OF THE GREAT PALMAR BURSA.

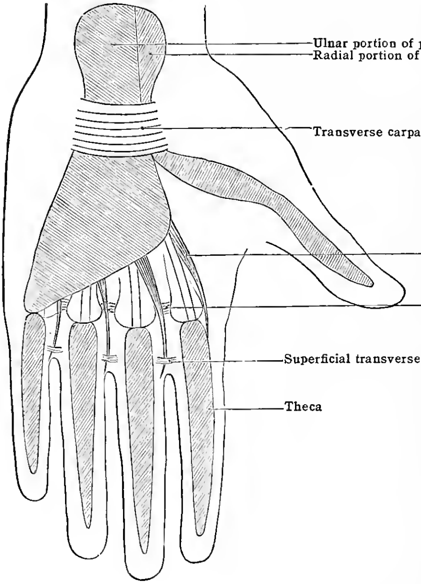


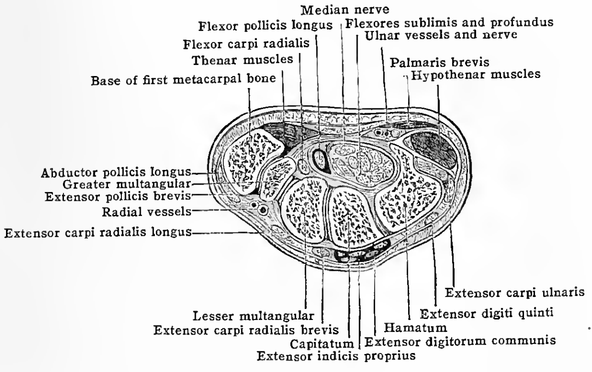
The **palmar aponeurosis,** by its strength, toughness, numerous attachments, and intimate connection with the superficial fascia and skin is well adapted to protect the parts beneath from pressure.

The thenar and hypothenar muscles are enclosed in two processes, which are thinner so as not to interfere with the contraction of the subjacent muscles. The central part, pointed above at its attachment to the carpal ligament, spreads out fan-like below, and gives off four slips, each of which bifurcates into two processes, which are attached to the sides of the first phalanx of each finger and into the superficial transverse ligament of the web and the deeper one which ties the heads of the metacarpal bones together. Transverse fibres pass between the processes into which each of the four slips bifurcates, and thus form the beginning of the theca, which is continued down the finger to the base of the last phalanx. It is the contraction of the palmar aponeurosis, especially of the slip to the two medial fingers, which gives rise to Dupuytren's contraction. The **theca** is strong opposite the first two phalanges (ligamentum vaginale), weak and loose opposite the joints (ligamentum annulare). The density of this osseo-fibrous tunnel and its close proximity to the digital nerves explain the pain in thecal inflammation. Its tendency to gape widely after section is to be remembered in amputations through infected parts.

Synovial membranes.—Beneath the transverse carpal ligament lie two **synovial sacs,** one for the flexor pollicis longus, and one for the superficial and deep flexors of the fingers. They extend above the transverse ligament for rather more than 2.5 cm. (1 in.). The two sacs may communicate. A compound palmar ganglion has an hour-glass outline, the transverse carpal ligament forming the constriction.

The creaking sensation in teno-synovitis and that of 'melon-seed' bodies often present in tuberculosis here is well known. The sheath for the long flexor of the thumb reaches to the base of the last phalanx. That for the finger-flexors gives off four processes. The one for the little finger also reaches to the base of the last phalanx. Those for the index-, middle, and **third** fingers end about the middle of the metacarpal bones. Traced from the insertions of the flexor

Fig. 1150.—Section of Carpus through the Hamate Bone. (Two-thirds.) (Bellamy, after Henle.)



profundus, the digital synovial sheaths extend upward into the palm as far as the bifurcation of the palmar fascia (p. 1430), i. e., into a point about opposite to the necks of the metacarpal bones, denoted on the surface by the crease which corresponds to the flexion of the fingers. Thus, about 1.2 cm. (½in.) separates the sheaths of the lateral three fingers from the large synovial sac beneath **the** transverse carpal ligament. There is no synovial sheath beneath the pulp of the fingers or thumb, this part lying on the periosteum of the last phalanx.

This has an important bearing on **whitlow.** Infection here may be merely *subcuticular*, or deeper, in the latter case from the connection of the skin with the periosteum here existing the bone is soon affected, and necrosis keeps up a tedious ulcer. As the two centres of the phalanx do not unite till about the twentieth year, the distal one only requires removal; as the flexor sheath only reaches to the insertion of the flexor, i. e., into the proximal, part of the bone, both sheath and tendon may escape implication. Higher up along the fingers whitlow may be *cellulo-cutaneous* or *thecal.* While the continuity of the synovial sheath in the little finger and thumb (fig. 1149) renders infection here more dangerous, the short gap between the digital and the palmar sacs is readily traversed by acute infection, with all the grave results of thecal suppuration.

Suppuration in the hand owes much of its gravity to the possibility of infection of the synovial tendon sheaths and consequent sloughing of the tendons. At the same time it is now recognised that unless these sheaths are primarily infected pus collects at first in certain potential spaces, more or less well defined, in the looser connective tissue of the hand. One of these, known as the **middle palmar space** (Kanavel*) is situated on the front of the metacarpals of the middle and ring fingers, and lies deeply between the flexor tendons and the interosseous muscles. Continuations of this potential space extend downward along the lumbrical muscles

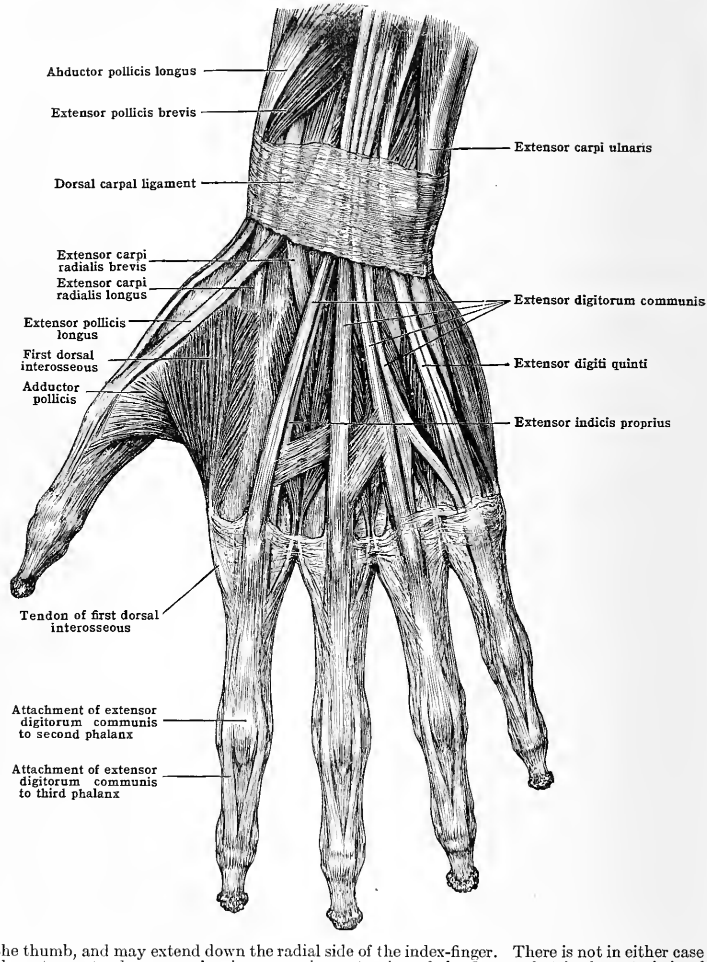
* Kanavel, A. B.: Infections of the Hand, 1912.

on the radial side of the three medial fingers, and may lead pus from the palm to the subcutaneous tissue of these fingers or *vice versa*. A second potential compartment, the **thenar space** (Kanavel) lies in front of the index metacarpal, between the flexors of the index-finger and the adductor transversus pollicis. As in the former space, the corresponding lumbrical muscle prolongs it down to the radial side of the index-finger.

Distention of the middle palmar space with pus leads to obliteration of the hollow of the palm and a variable extension of the swelling along the radial side of the three medial fingers. Distention of the thenar space follows the thenar eminence, obliterates the adduction crease of

FIG. 1151.—TENDONS UPON THE DORSUM OF THE HAND.

(The dorsal expansion or aponeurotic sheath has not been removed.)



the thumb, and may extend down the radial side of the index-finger. There is not in either case the extreme tenderness and pain on passive extension of the fingers that is characteristic of infection of the synovial sheaths. The pus is best evacuated by an incision on the radial side of the finger most affected, a little behind the web, sinus forceps being passed along the lumbrical muscle into the palm, so as to avoid opening and infecting the synovial sheaths.

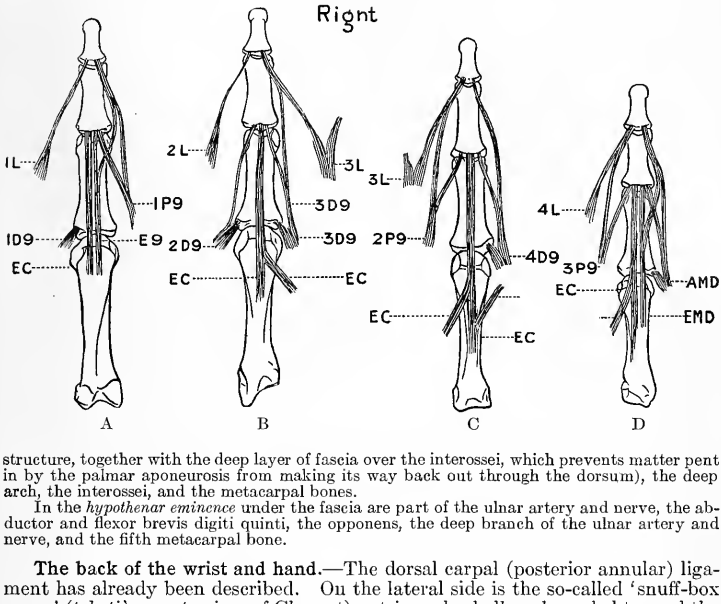
It must be remembered also that infection of the above fascial spaces may take place secondarily, by the bursting into them of pus from the synovial tendon sheaths.

Deeper are the **articular synovial sacs,** five in number:—(1) Between the interarticular cartilage and the head of the ulna; (2) between the radius and the interarticular cartilage above, and the navicular and lunate and triquetrum below; (3) between the greater multangular and first metacarpal bone; (4) between the pisiform and the triquetral bone; (5) between the two rows of carpal bones, sending two processes upward between the three bones of the upper row, and three downward between the four of the lower row; these three processes being also continued below into the medial four carpo-metacarpal and three intermetacarpal joints.

Beneath the palmar aponeurosis covering the *thenar eminence* are the following structures:—Superficial volar artery, abductor pollicis brevis, opponens pollicis, radial head of short flexor, tendon of long flexor, ulnar head of short flexor, first volar metacarpal arteries, metacarpal bone of the thumb, with the tendon of the flexor carpi radialis and greater multangular.

Beneath the *central part* of the palmar aponeurosis are the superficial arch and its digital branches; the ulnar and median nerves, with their branches; the flexors, superficial and deep, with their synovial sheath; and the lumbricales; then a layer of connective tissue (the only structure, together with the deep layer of fascia over the interossei, which prevents matter pent in by the palmar aponeurosis from making its way back out through the dorsum), the deep arch, the interossei, and the metacarpal bones.

Fig. 1152.—Diagrams Illustrating the Insertions of the Extensor, Lumbrical and Interosseous Muscles of the Right Hand. A, Index finger. B, Middle finger. C, Ring finger. D, Little finger. 1L, 2L, 3L, 4L, Lumbricales. 1D9, 2D9, 3D9, 4D9, dorsal interossei. 1P9, 2P9, 3P9, palmar (volar) interossei. EC, Extensor communis digitorum. E9, Extensor indicis proprius. EMD, Extensor digiti quinti proprius. AMD, abductor digiti quinti (Willan: Anat. Anz. Bd. 42, 1912.)



In the *hypothenar eminence* under the fascia are part of the ulnar artery and nerve, the abductor and flexor brevis digiti quinti, the opponens, the deep branch of the ulnar artery and nerve, and the fifth metacarpal bone.

The back of the wrist and hand.—The dorsal carpal (posterior annular) ligament has already been described. On the lateral side is the so-called 'snuff-box space' (*tabatière anatomique* of Cloquet), a triangular hollow, bounded toward the radius by the long abductor and short extensor of the thumb, and toward the ulna by the long extensor. The navicular and greater multangular, with their dorsal ligaments, form the floor. In the roof lie the radial vein and branches of the radial nerve. More deeply is the artery, following a line from the apex of the styloid process to the back of the interosseous space.

The different tendons have already been given. Between the first two metacarpal bones is the first dorsal interosseous muscle, which forms a fleshy projection against the radial side of the index metacarpal, when the thumb and index are pressed together. On its palmar aspect is the adductor pollicis. Wasting of the former muscle is a ready indication of injury or disease of the ulnar nerve.

The skin on the dorsum, by its laxity, readily allows of œdema, this being sometimes evidence of pressure on the axillary vein by carcinomatous deposits. The dorsal venous arch receives the digital plexuses, and from it the radial and posterior ulnar veins ascend. The median vein begins in plexuses at the root of the thumb and the front of the wrist.

Ganglia are common on the dorsum, in connection with the extensors of the fingers and the thumb. While usually due to a weakening of the sheath and protrusion of this and the synovial membrane, such swellings may be due to a projection of the articular synovial membrane. Owing to the laxity of the skin, the slight vascularity, the size of the tendons, their connection with joint-capsules and with each other, which fixes them, the dorsum of the wrist is the 'seat of election,' for **tendon-anastomosis** and other operations. **Metacarpo-phalangeal dislocation.** This occurs in the thumb and the index-finger especially. The chief cause in the difficulty in reduction is the glenoid ligament. This, in reality a fibro-cartilaginous plate, is blended with the lateral ligaments on the palmar aspect of the joint, and is firmly attached to the phalanx, but more loosely to the metacarpal. Thus when dislocation occurs in violent hyperextension, the metacarpal attachment of the glenoid ligament gives way and it is carried by the phalanx over the head of the metacarpal bone. In the case of the thumb, the buttonhole-like slit with which the two heads of the flexor brevis, now displaced, embrace the head of the metacarpal, the contraction of the other short muscles, and, occasionally, a displaced long flexor, are additional causes. In the case both of the thumb and finger, tilting the phalanx well back on the dorsum of the metacarpal and then combined pressure with the thumbs forward against the base of the phalanx, when this is sharply flexed, will with an anæsthetic, be usually successful. The thumb should be, first, adducted into the palm.

THE LOWER EXTREMITY

HIP AND THIGH

The various segments of the lower extremity will be successively considered as follows: hip and thigh, knee and leg, ankle and foot.

Bony landmarks.—Many of these, such as the anterior superior iliac spine and crest of the ilium and the tubercle of the pubis, have already been mentioned. The relative length of the limbs is obtained by carrying the measure from the anterior superior spine to the tip of the corresponding medial malleolus. The pelvis must be horizontal and the limbs parallel. The share taken by the femur and tibia respectively is estimated by finding the transverse sulcus which marks their meeting-point.

The head and shaft of the **femur** are well covered in, save in the emaciated. The head lies just below Poupart's ligament, under the ilio-psoas, and a little to the outer side of the centre of that ligament. A line drawn horizontally laterally from the pubic tubercle will cross the lower part of the head. All the head and the front of the neck, but only two-thirds of the back, are within the capsule; this intra-capsular position of the upper epiphysis, which, appearing at the first year, does not unite till eighteen or twenty, accounts largely for the extreme gravity of acute epiphysitis here. The structure of the neck, i. e., the two sets of lamellæ, *vertical* to support the weight, *transverse* and *intersecting* in order to meet the pull of the muscles, and the wasting of these after middle life, has an important influence on injuries. The strong process, *femoral spur* or *calcar* (Merkel) which, arising from the compact tissue on the medial and under side of the neck, just above the lesser trochanter, spreads laterally toward the trochanteric (digital) fossa, also affords strength, and its degeneration probably plays an important part in the fractures of the neck.

Hip-joint.—The chief points of surgical importance are the following:—The capsule shows fibres chiefly longitudinal in front, circular behind. Of the former, the ilio-femoral or inverted **Y**-shaped ligament descends from the anterior inferior spine to the two extremities of the anterior intertrochanteric line. It not only checks extension and strengthens the front of the joint, but it keeps the pelvis and trunk propped forward on the heads of the femurs, thus preventing waste of muscular action. It is joined on the medial side by the pubo-capsular ligament, which checks abduction. Between the two is the medial part of the front capsule, and here the ilio-psoas bursa may communicate with the joint. This fact must be remembered in tuberculous disease of the psoas, and the presence of this bursa explains certain deep-seated swellings in the front of the joint in adults. Behind, the ischio-femoral is the strongest part of the capsule, its fibres blending with the circular and weaker part of the capsule here. Dislocation usually occurs at the posterior, lower and medial part of the joint. It is to be noted that in full extension and flexion the head of the femur is in contact with the weakest spot in the capsule, in front and behind, respectively. From the deep aspect of the capsule fibres pass up at the line of reflection of the synovial membrane on to the neck—the cervical ligaments of Stanley. In intracapsular fracture these fibres keep the fragments together; hence one need of gentle handling; their softening may explain, a little later, an increase in the shortening.

Exploration of the joint.—This is usually effected by an oblique incision downward and slightly medially between the sartorius and rectus medially and the gluteus medius and minimus laterally. A branch of the ascending division of the lateral circumflex is the only artery met with. In tapping the joint the puncture is made in the same line, 2 or 3 inches below the anterior-superior spine. 'If the instrument is pushed upward, medially, and backward beneath the rectus, it will pass into the joint a little above the anterior intertrochanteric line. (Stiles.)

Fig. 1153.—Region of the Hip-joint, as Shown by the Röntgen-rays.

Trochanter major.—This valuable landmark is most prominent when the limb is rotated medially or adducted; it lies at the bottom of a depression when the femur is everted.

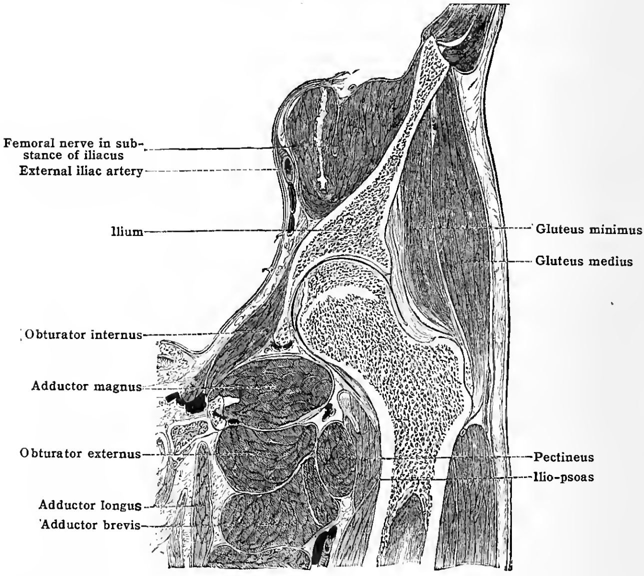
The chief structure of importance between it and the skin is the upper part of the insertion of the gluteus maximus, that going to the fascia lata, and the bursa beneath the muscle. This is often multilocular. It is, not very uncommonly, the seat of tubercular inflammation which readily invades the cancellous tissue of the trochanter. The top of the great trochanter is about 1.8 cm. ($\frac{3}{4}$ in.) below the level of the femoral head, and, when the femur is extended is a little below the centre of the hip-joint. This part of the bone is covered by the gluteus medius.

The slightness of the prominence of the great trochanter in the living subject compared with that in the skeleton is explained by fig. 1154, which shows how the descending gluteus medius and minimus fill up the space between the ilium and trochanter. To examine the great trochanter, the thigh should be abducted, so as to relax the strong fascia lata passing upward over the tensor and glutei to the iliac crest.

Nélaton's line.—This useful guide is a line drawn from the anterior superior spine of the ilium to the most prominent part of the tuberosity of the ischium. In normal limbs, the top of the great trochanter just touches this line. In dislocation, fractures of the neck, and in wasting of the neck, as in osteo-arthritis, the relation of the trochanter to Nélaton's line becomes altered.

The top of the great trochanter is a guide in Adams's operation for division of the neck of an ankylosed femur, the puncture being made and the saw entered 2.5 cm. (1 in.) above and about the same distance in front of this point. Owing to the fact that in many cases of ankylosis the neck is destroyed, the above operation has been largely replaced by the simpler and more widely applicable Gant's osteotomy just below the great trochanter, from the lateral side.

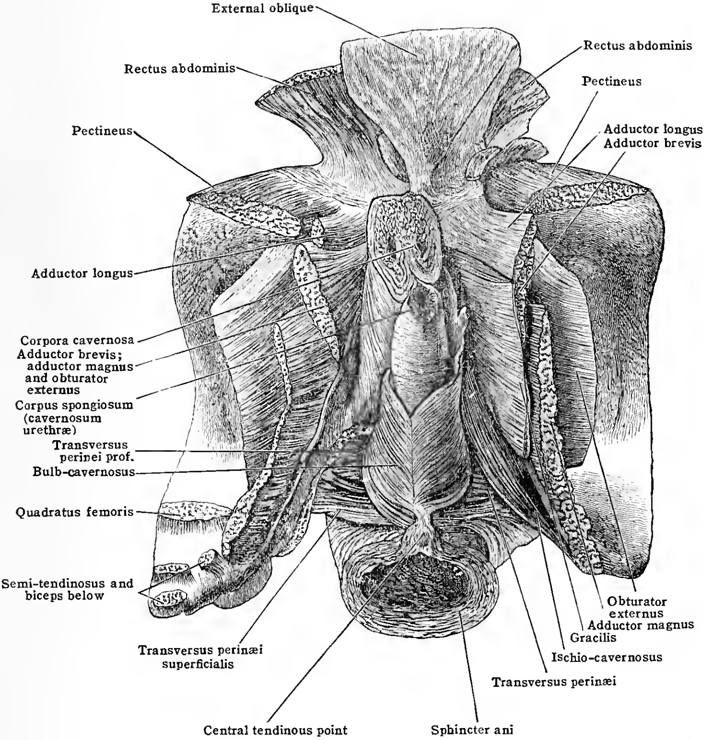
FIG. 1154.—TRANSVERSE SECTION OF THE HIP-JOINT AND ITS RELATIONS. (One-third.) (Braune.)



Bryant's triangle.—Bryant makes use of the following in deciding the position of the great trochanter. The patient being flat on his back (1) a line is dropped vertically on to the couch from the anterior superior spine; (2) from the top of the great trochanter a straight line in the long axis of the thigh is drawn to meet the first; (3) to complete the triangle, a line is drawn from the anterior superior spine to the top of the trochanter. This line is practically Nélaton's. The second line will be found diminished on the damaged or diseased side.

Muscular prominences.—The *tensor fasciæ latæ* forms a prominence beginning just lateral to the sartorius and reaching downward and somewhat backward to the strong fascia lata, 7.5 to 10 cm. (3 to 4 in.) below the great trochanter. Below this point, as far as the lateral condyle of the tibia, the strong *ilio-tibial band* can be felt. Like the inverted Y-shaped ligament, this band is a powerful saving of muscular action in maintaining the erect position. At the insertion of the tensor fasciæ latæ it bifurcates into two layers, which enclose the muscle. The superficial is attached to the iliac crest and the sheath of the gluteus medius; the deep blends with the capsule and the reflected head of the rectus. This deeper layer is perforated by the ascending branch of the lateral circumflex. The ilio-tibial band is a guide for reaching the femur (p. 1334). The *sartorius*, the chief landmark of the thigh, forming a boundary of the femoral trigone (Scarpa's triangle), the adductor (Hunter's) canal, and the popliteal space, can be readily brought into view by the patient's raising his limb slightly rotated laterally. In the middle line the *rectus* muscle stands out in bold relief, with its tendon of insertion and the patella, when the leg is extended. On either side of this muscle is a furrow, and on either side, again, of this furrow the *vasti* become prominent. Between the vastus medialis and adductor muscles is a depression indicating the adductor canal. At the upper and medial third of the thigh, if the limb be abducted, the upper part of the *adductor longus* comes into strong relief. On the medial side below, above the knee-joint, the vertical fibres of the *adductor magnus* end in a powerful tendon coming down to the adductor tubercle (fig. 1159). This replaces here the medial intermuscular septum, and the insertion of the tendon marks the level of the lower epiphysial line of the femur. At the lateral and back part of the thigh the vastus lateralis is separated from the biceps by a groove which indicates the lateral intermuscular septum. Of these septa, prolongations inward from the fascia lata to the linea aspera, the lateral lies between the vastus lateralis and the biceps. It reaches from the lateral tuberosity of the femur to the insertion of the gluteus maximus. Just above the condyle it is perforated by the superior lateral articular vessel and nerve. The medial septum extends from the adductor tubercle to the trochanter. It is weak in

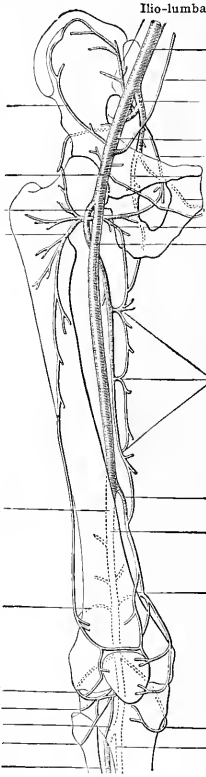
FIG. 1155.—THE MUSCLES ATTACHED TO THE PUBES.
(From a dissection in the Hunterian Museum.)



comparison, and separates the adductor from the vastus medialis. A **third,** the weakest of all, separates the adductor and the hamstrings. The **fascia lata** has the same effect as that in the neck in causing pus to burrow, especially downward, and in rendering the diagnosis of swellings beneath it difficult. Thickest above and on the lateral aspect, and again about the bony prominences at the knee-joint, at both of which sites it receives accessions from muscles, it is divided into **iliac** and **pubic portions.** The former is attached behind to sacrum and coccyx, iliac crest and the inguinal ligament, terminal line and pubic tubercle. Here it blends with the pubic portion, which is connected with the pubic arch. At the fossa ovalis (saphenous opening) the two may be said to separate, the iliac forming the upper cornu and lateral falciform margin, and descending over the femoral vessels and extensors. The pubic, much thinner, forms the medial margin of the fossa, and descends obliquely over the pectineus and adductor longus behind the vessels, to blend with the sheath of the ilio-psoas and capsule of the hip-joint.

The **inguinal (Poupart's) ligament.**—The abdomen is separated from the thigh by a fold, best marked in flexion—the inguinal furrow. In this, pressure detects the meeting of the aponeurosis of the external oblique and the fascia lata, i. e., Poupart's ligament, extending between the anterior superior spine of the ilium and the tubercle (spine) of the pubes. The line representing it should be drawn slightly convex downward, owing to the attachment of the deep fascia. It forms the base of the femoral trigone; its medial attachment blends with the triangular lacunar (Gimbernat's) ligament. The parts passing under the inguinal ligament and their arrangement have been given at p. 1399, fig. 1122.

Fig. 1156.—Diagram of Arteries of Thigh.



The **femoral trigone (Scarpa's triangle)** (fig. 1159).—Immediately below the inguinal ligament a hollow is seen corresponding to this region, the lateral and medial boundaries of which are brought into view when the limb is raised, the adductor longus especially when the limb is abducted, and the sartorius when the thigh is flexed and the limb extended and rotated laterally. The floor of the femoral trigone is not horizontal, the plane of the medial part being very oblique. It is formed latero-medially by the ilio-psoas, pectineus, adductor brevis (slightly), and adductor longus.

A **psoas abscess** descending below the inguinal ligament usually does so on the lateral aspect of the femoral vessels; if the sheath gives way, or if the abscess follows the profunda artery, it will pass beneath the adductor longus and point toward the medial side of the thigh. (Taylor.)

FIG. 1157.—SECTION OF THE RIGHT THIGH AT THE APEX OF THE FEMORAL TRIGONE. (Heath.)

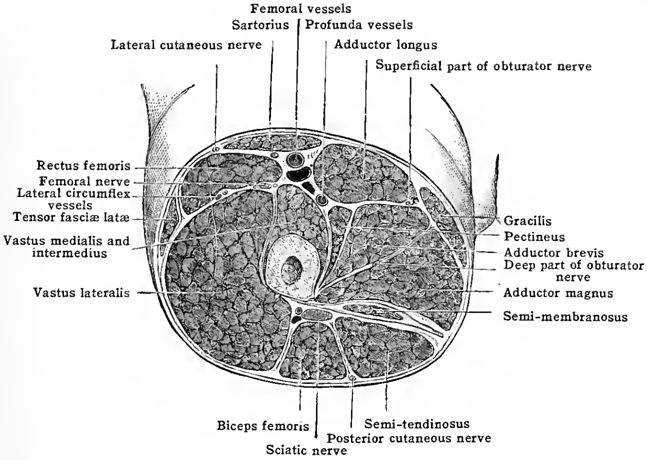


FIG. 1158.—SUPERFICIAL DISSECTION OF THE FRONT OF THE THIGH. (Hirschfeld and Leveillé.)

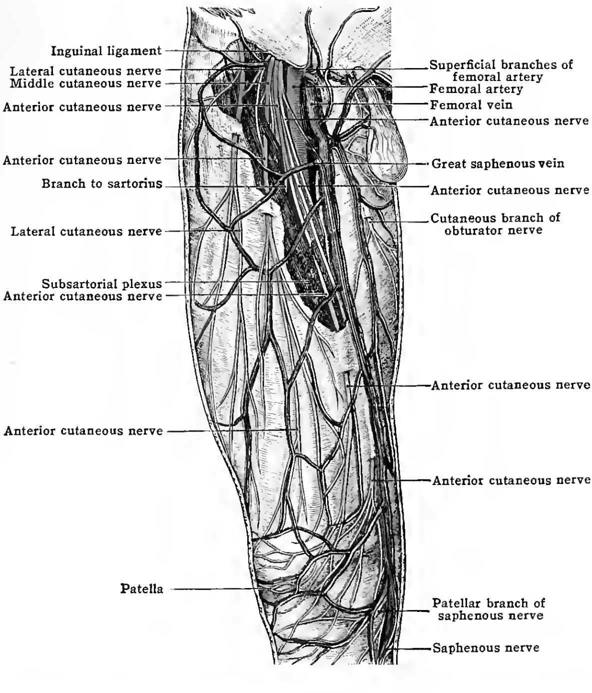
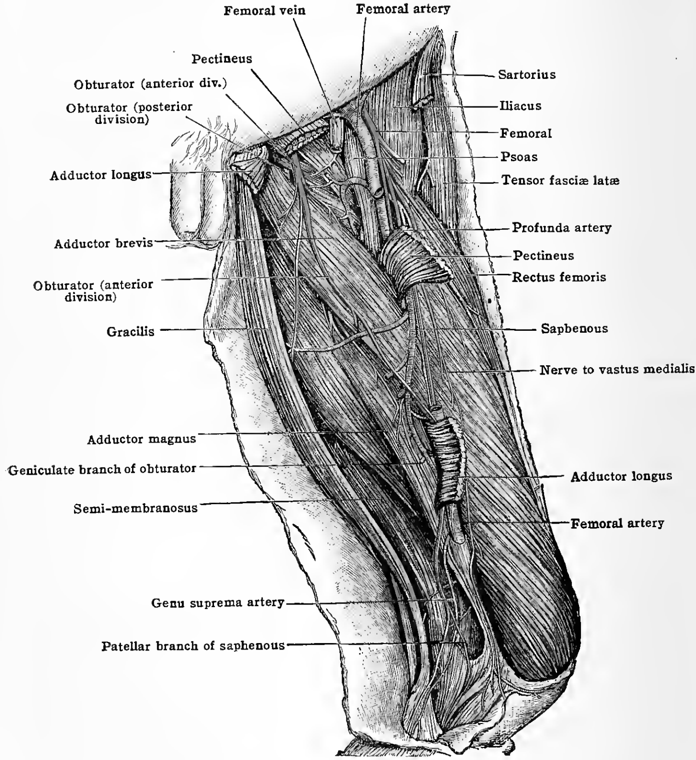


If it simulate a femoral hernia, examination of the back and the fact that the swelling is below the fossa ovalis will prevent mistakes. Three nerves come into the thigh between the pelvis and Poupart's ligament, i. e., the lumbo-inguinal (genito-crural) in the femoral sheath, the femoral (anterior crural) between the iliacus and psoas and the lateral cutaneous close to the lateral attachment of the inguinal ligament.

The **obturator nerve** divides into two in the obturator foramen, the two divisions being separated by some fibres of the obturator externus, and lower down by the adductor brevis. The relations, course, and distribution of this nerve, in the medial fibres of the psoas, over the sacro-iliac joint and under the ilio-pelvic or sigmoid colon (Hilton), through the obturator foramen with its branches (from the superficial division) through the cotyloid notch to the hip, and (from the deep)

Fig. 1159.—Femoral and Obturator Nerves. (Ellis.)



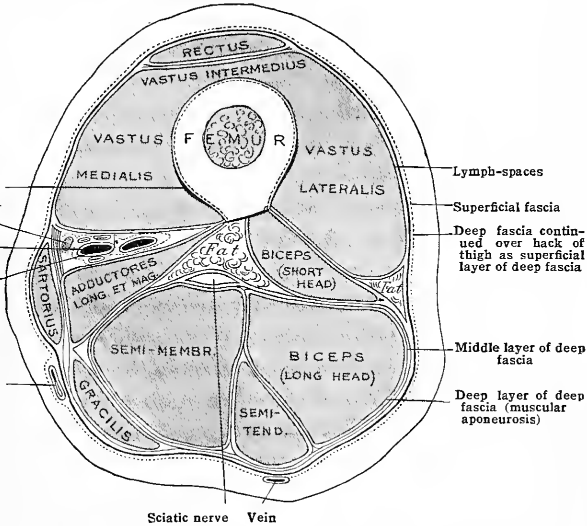
along the popliteal artery to the knee, and others to the lower third of the thigh, and sometimes the upper and medial aspect of the leg (Hilton), may be of much surgical importance, e. g., in carcinoma of the bowel, disease of the sacro-iliac and hip-joints, growths of the pelvis, and the rare obturator hernia. The distribution of the **cutaneous nerves** is shown in fig. 1158. Lying superficially in the base of the trigone, the **inguinal lymphatic nodes** can be detected in a thin person (fig. 1172).

The **fossa ovalis (saphenous opening)**.—The depression corresponding to this is placed just below the lacunar (Gimbernat's) ligament, with which its upper extremity blends. Its centre is about 3.7 cm. ($1\frac{1}{2}$ in.) below and also lateral to a line dropped vertically from the pubic tubercle. This and the other structures concerned in femoral hernia are fully described under this section (*vide supra*, p. 1398). The course of the great saphenous vein is given below, p. 1456.

Line of femoral artery.—A line drawn from the mid-point between the anterior superior spine and the symphysis pubis to the adductor tubercle will correspond with the course of this vessel. The sartorius usually crosses it 10 cm. (3 to 4 in.) below the inguinal (Poupart's) ligament. The profunda artery arises usually 3.7–5 cm. ($1\frac{1}{2}$ to 2 in.) below Poupart's ligament.

The incision for tying the femoral in the femoral trigone should be about 7.5 cm. (3 in.) long, in the line of the artery, and begins about 7.5 cm. (3 in.) below the inguinal ligament, and runs over the apex of the triangle. The femur is flexed slightly, abducted and rotated laterally. The fascia lata being divided, the sartorius, readily recognised by its direction, is drawn laterally. The closely subjacent sheath must be opened on its lateral side. Structures that may be seen are a vein joining the great saphenous, the anterior cutaneous, saphenous nerve, and that to the vastus medialis. The collateral *circulation* (fig. 1156) is mainly through the following

Fig. 1160.—Section of Thigh through upper Part of Hunter's Canal. (W. A.)



channels:—(1) The lateral and medial circumflex above, with the genu suprema and lower muscular branches of the femoral, and the articular of the popliteal. (2) The perforating branches of the profunda above, with the vessels below first given. (3) The comes nervi ischiadici with the articular of the popliteal.

The femoral **vein** lies, below the inguinal ligament, immediately to the medial side of the artery. From this point on the vein gets to a somewhat deeper plane, though still very close to the artery, and gradually inclining backward, lies behind its companion at the apex of the triangle, and below lies somewhat laterally to it.

From the apex of the femoral trigone (Scarpa's triangle) a depression runs down along the medial aspect of the thigh, corresponding to the groove already mentioned between the vastus medialis muscle and the adductors. Along this groove lies the sartorius, and beneath it the **adductor (Hunter's) canal,** a triangular inter-muscular gap with its apex toward the linea aspera, and its base or roof formed by the fibrous expansion which ties together its boundaries, viz., the adductor longus and magnus and the vastus medialis.

The vein, which in the upper part of the canal lies behind the artery, separating it from the three adductors, lower down inclines more and more to the lateral side. The saphenous nerve lies also in the canal, but not in the sheath. The above-mentioned space terminates at about the junction of the middle and lower thirds of the thigh, in the opening in the adductor magnus by which the artery enters the upper and medial part of the popliteal space. The saphenous, the largest branch of the femoral nerve, having crossed the femoral vessels latero-medially, accompanies them as far as the opening in the adductor magnus. Here it perforates the aponeurotic roof, and is prolonged under the sartorius, accompanied by the superficial part of the genu suprema artery, to perforate the fascia lata between the sartorius and gracilis, and run with the great saphenous vein at the upper and medial part of the leg.

Pressure may be applied to the femoral artery—(1) Immediately below the inguinal ligament: it should here be directed backward so as to compress the vessel against the brim of the pelvis and the capsule of the hip-joint; (2) at the apex of the femoral trigone the pressure here being directed laterally and a little backward, so as to command the vessel against the bone; (3) in the adductor canal the pressure should be directed laterally with the same object. Care must be taken, especially above, to avoid the vein, which lies very close to the artery, and also the femoral nerve, which enters the thigh about 1.2 cm. ($\frac{1}{2}$ in.) outside the artery, and at once breaks up into its branches, superficial and deep.

In ligature of the femoral artery in Hunter's canal, the line of the incision, in the middle third of the thigh, must exactly follow that of the vessel. It is frequently made too lateral, exposing the vastus medialis. Branches of the saphenous vein being removed, the fascia lata is slit up and the sartorius identified by its fibres descending medially. Those of the vastus medialis are less oblique and are directed downward and laterally. The sartorius having been drawn to the medial side, usually, the aponeurotic roof of the canal is opened, and the femoral sheath identified. The vein, here posterior and to the lateral side, is closely connected to the artery.

The close contiguity of the femoral artery and vein accounts for the comparative frequency of arterio-venous aneurysms especially in the upper part, where the vessels are easily wounded. Their superficial position here further accounts for the facility with which malignant disease, e. g., epitheliomatous glands, may cause fatal hæmorrhage. **Access to the femur.** This is best attained on the lateral side of the shaft along the line of the lateral intermuscular septum (fig. 1160), the biceps being pulled backward, and the vastus lateralis detached anteriorly. On the medial side the bone may be exposed by an incision starting from a point midway between the inner margin of the patella and the adductor tubercle and passing obliquely upward and laterally, but the parts here are more vascular. **Fractures of the shaft** usually occur about the centre. The main tendency to displacement is of the lower fragment upward by the hamstrings. The upper fragment is anterior; this is especially marked in the upper third, owing to the action of the ilio-psoas, which also rotates the upper fragment laterally. In the lower third the forward curve of the femur and its more superficial position explain the fact that it is here that compound fractures of the femur may, occasionally, occur. **Ossification.** The unstable nature of the tissues about the upper epiphysis, which appears at the end of the first year and unites about eighteen, and the frequency of tuberculous disease in early life are well known. In the lower epiphysis ossification begins before birth, a point of medico-legal importance in deciding whether a newly born child has reached the full period of uterine gestation. From this epiphysis, the level of which is denoted by a line drawn horizontally laterally from the adductor tubercle, and the vascular growing tendon of the adductor magnus—the origin of an exostosis is not uncommon. **Displacement of this epiphysis** (it unites about twenty) in boyhood and adolescence is a grave injury from the immediate risk of the popliteal vessels. The mischief is usually done by overextension of the leg, as when this is caught in a rapidly moving carriage-wheel; the epiphysis is carried forward in front of the diaphysis, the lower end of which is directed backward, endangering the vessels which are posterior and closely adjacent.

Amputation through the thigh.—This is usually performed in the lower third, by anterior and posterior flaps, the former being the longer, so as to ensure a scar free from pressure, and circular division of the muscles, vessels, and nerves. The vessels requiring attention are the femoral, which lie at the medial side, and the more posteriorly, the lower the amputation; the descending branch of the lateral circumflex, and the termination of the profunda near the linea aspera. The femoral artery has a marked tendency to retract in the adductor canal. Care should be taken not to include the saphenous nerve when the femoral vessels are tied, and to cut the sciatic cleanly and high up. When amputation has to be performed in the upper third of the thigh, the tendency of the ilio-psoas to flex the shortened limb and thus bring the sawn femur against the end of the stump must be remembered, and met by keeping the patient propped up and the stump as horizontal as possible. Some of the structures now divided are shown in fig. 1160.

The buttocks. Bony landmarks.—The finger readily traces the whole outline of the iliac crest. Behind, it terminates in the posterior superior iliac spine, which corresponds in level to the second sacral spine and the centre of the sacro-iliac joint. (Holden.)

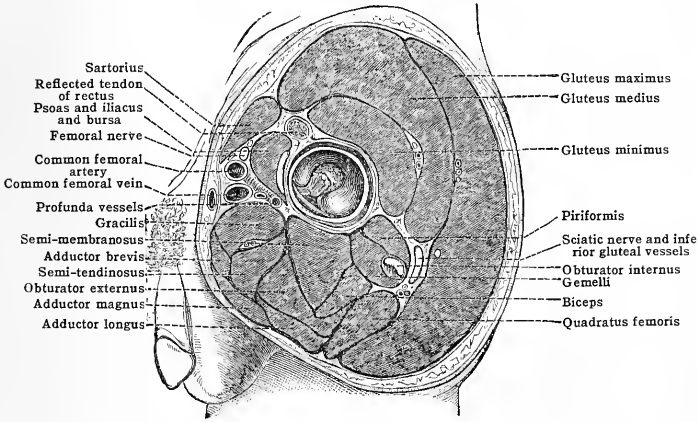
The third sacral spine marks the lowest limit of the spinal membranes and the cerebro-spinal fluid; it also corresponds to the upper border of the great sacro-sciatic notch. The first piece of the coccyx corresponds to the spine of the ischium. (Windle.) Its apex is in the furrow just behind the last piece of the rectum.

The tuberosities of the ischium are readily felt by deep pressure on either side of the anus. In the erect position they are covered by the lower margin of the gluteus maximus. In sitting they are protected by tough skin, fasciæ, with coarse fibrous fat, and often by a bursa known, according to the patients in whom it becomes enlarged, as weaver's, coachman's, lighterman's, drayman's bursa. The skin of the buttock is coarse and difficult to cleanse satisfactorily. The abundance of sebaceous glands accounts for the frequency of boils here.

Gluteus maximus.—The 'fold of the buttock' neither corresponds accurately to, nor is caused by, the lower margin of this muscle. Thus, medially, it lies below the lower margin of the muscle, as it runs laterally it crosses it, and comes to lie on the muscle. The fold is really due to creasing of the skin adherent here to the coarsely fibro-fatty tissue over the tuber ischii during extension. But in early hip disease, in which flexion of the joint is, with wasting of the muscle, almost unvaryingly present, the fold disappears with well-known rapidity. The prominence of the buttock is mainly due to the gluteus maximus, especially behind and below, and in less degree to the other two glutei in front. Under the lower edge of the gluteus maximus the edge of the sacro-tuberous (great sacro-sciatic) ligament can be felt on deep pressure.

To mark out the upper border of the **gluteus maximus** a line is drawn from a point on the iliac crest 5 cm. (2 in.) in front of the posterior superior spine, downward and laterally to the back of the great trochanter. The lower border is marked out by a second line drawn from the side of the coccyx parallel with the former, and ending over the linea aspera at the junction of the upper and middle thirds of the thigh. It must be remembered that only the lower and internal fibres of the muscle are inserted into the gluteal ridge on the femur. The greater part of

Fig. 1161.—Section through the Hip and Gluteal Region. (One-third.)



it is inserted into the fascia lata and ilio-tibial band and so into the lateral condyle of the tibia. Weakness of the gluteus maximus and tensor fasciæ latæ, with consequent laxity of the ilio-tibial band, gives rise to abnormal side-to-side passive mobility at the knee-joint in full extension.

Nerves and vessels.—The following **superficial nerves** can be marked in over the buttock (fig. 1182).

Behind the great trochanter, branches of the lateral cutaneous; coming down over the crest, the lateral cutaneous branch of the last thoracic (about in a line with the great trochanter), and behind this the lateral branch of the ilio-hypogastric. Two or three offsets of the posterior primary branches of the lumbar nerves cross the hinder part of the iliac crest at the lateral margin of the sacro-spinalis. Two or three twigs from the posterior divisions of the sacral nerves pierce the gluteus maximus close to the coccyx and sacrum, and ramify laterally. Finally, over the lower border of the gluteus maximus, turn upward branches of the posterior cutaneous (small sciatic) and its perineal branch (inferior pudendal), and the fourth sacral nerve.

Sciatic nerve (figs. 1162, 1163).—The point of emergence below the gluteus maximus and the track of this nerve (fourth and fifth lumbar and first three sacral nerves) will be given by a line drawn from a spot a little medial to the middle of the space between the great trochanter and the tuber ischii to the lower part of the back of the thigh, where it usually divides into the tibial and common peroneal (internal and external popliteal) nerves.

To stretch the nerve, an incision about three inches long is made in the line of the nerve, beginning about 3.7 cm. ($1\frac{1}{2}$ in.) below the gluteus maximus. The long head of the biceps which covers the nerve trunk and which is descending mediolaterally, is drawn medially. If the nerve is exposed lower down, the interval between the hamstrings is identified and these muscles drawn aside. The perineal branch of the posterior cutaneous (inferior pudenal) perforates the deep fascia about 2.5 cm. (1 in.) in front of the tuber ischii, and turns forward to supply the genitals.

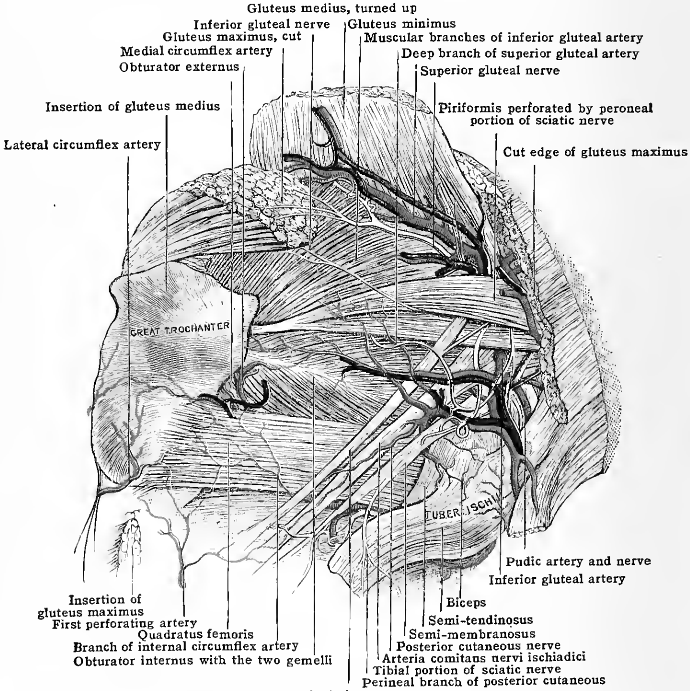
Superior gluteal artery.—If a line be drawn from the posterior superior spine to the apex of the great trochanter, the limb being slightly flexed and rotated medially, the point of emergence of the artery from the upper part of the great sacro-sciatic notch will correspond with the junction of the upper and middle third of this line. (MacCormac.) The gluteal nerve emerges immediately below the artery, and sends branches into the deeper portion.

Inferior gluteal (sciatic) and pudic arteries.—The limb being rotated medially, a line is drawn from the posterior superior spine to the lateral part of the tuber ischii. The point of exit of the above arteries will correspond to the junction of the middle and lower thirds of this line. (MacCormac.)

THE KNEE

Bony landmarks.—The patella, the condyles of the femur, the condyles and tuberosity of the tibia, the head of the fibula, are all easily examined.

Fig. 1162.—The Gluteal Region, with the Superior and Inferior Gluteal and Pudic Arteries.

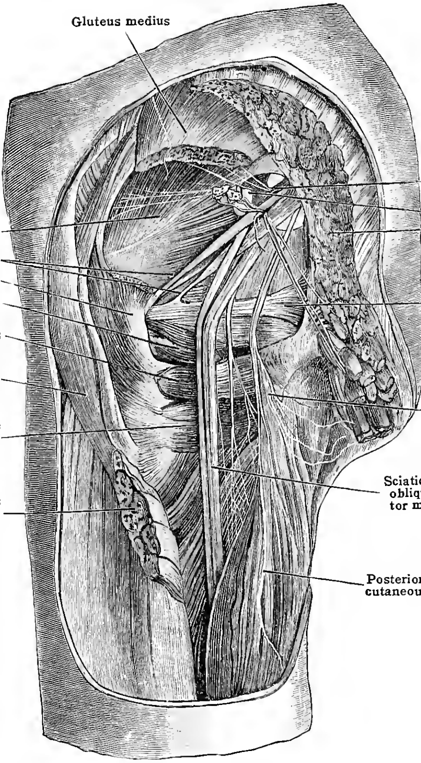


(From a dissection by W. J. Walsham in St. Bartholomew's Hospital Museum.)
The muscular branch of the inferior gluteal (sciatic) artery has been drawn inward over the tuber ischii with the reflected origin of the gluteus maximus muscle.

The patella.—The limb being supported in the straight position, and the extensor muscles relaxed, the natural range of mobility laterally of the patella can be estimated. This is interfered with by muscular action in inflammatory conditions, or by early tuberculous ulceration of the contiguous cartilages. The numerous longitudinal striæ or sulci on the anterior surface of this bone can now also be detected. In these are embedded tendinous bundles of the rectus, so as to give firmer leverage. The fact that these fibres, thus tied down, are liable after stretching and tearing to fold in between the ends of the bone after fracture, is a ready explanation of the difficulty of ensuring bony union here. (Macewen.) The patella is separated from the tibia by a pad of fat and a deep bursa, save at its insertion. Owing to the lowest part of the patella being thus separated from the joint by fat, fracture here does not, necessarily, open the joint.

The bone has the following *relation to the femur* in different positions:—(1) In **extension**, the patella rises over the condyles, and in full extension only the lower third of its articular surface rests upon that of the condyles; its upper two-thirds lies upon the bed of fat which covers the

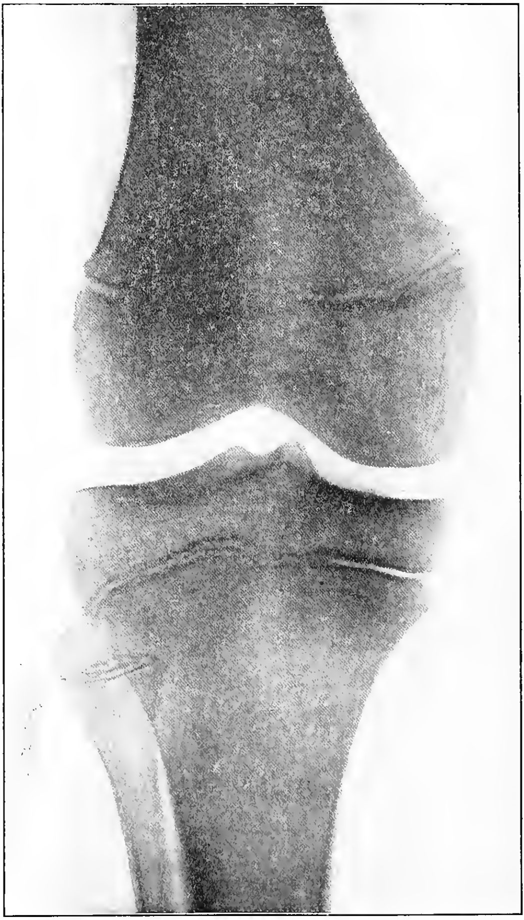
Fig. 1163.—Deep Dissection of the Gluteal Region. (From a preparation in the Hunterian Museum.)



lower and front part of the femur. (2) In extreme **flexion**, as the prominent anterior surface of the condyles affords leverage to the quadriceps, the patella needs to project very little; thus, only its upper third is in contact with the femur, its lower two-thirds now resting on the pad of fat between it and the tibia. (3) In **semiflexion** the middle third of the patella rests upon the most prominent part of the condyles. (Humphry.) While the bone now affords the greatest amount of leverage to the quadriceps, it is also submitted to the greatest amount of strain from this muscle, which is acting almost at a right angle to the long axis of the patella. This position may therefore be called the 'area of danger,' as, in a sudden and violent contraction, the patella may be snapped across by muscular action, aided by the resistance given by the condyles, in the same way as a stick is snapped across the knee. The amount of separation of the fragments in a fracture of the patella is due chiefly to the extent to which the lateral tendinous expansions of the vasti are torn; to a less degree to the hæmorrhage from the numerous articular vessels (p. 1452) and synovial effusion. The lower fragment is usually the smaller, and its fractured surface tilted forward; that of the upper one usually looks backward.

The patella, the largest of the sesamoid bones, ossifies by a centre which appears from the third to the fifth year. The process is completed about puberty. The rareness with which necrosis and caries occur here, when the exposed situation of the bone is remembered, is partly

Fig. 1164.—Knee-joint as Shown by the Röntgen-rays, Antero-posterior View.

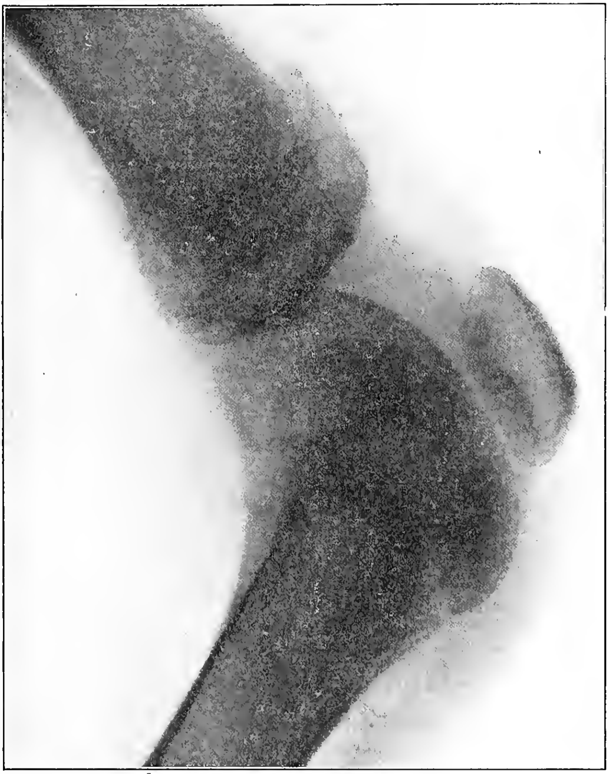


explained by the density of its tissue, especially in front, and the intimate blending of the rectus fibres with its periosteum. When the knee-joint is bent, the trochlear surface of the femur can be made out, with some difficulty, underneath the quadriceps expansion. The upper and lateral angle of this surface forms a useful landmark (Godlee) as a line drawn from it to the adductor tubercle marks the level of the lower epiphysis of the femur.

Dislocation of the patella.—The following anatomical facts account for this taking place much more frequently laterally:—(1) The medial edge of the patella is more prominent, and thus more exposed to injury; it is also well supported, as is seen when, the parts being relaxed, the fingers are insinuated beneath each border. (2) The pull of the extensor upon the patella, ligamentum patellæ, and tibia is somewhat laterally, as the tibia is directed a little laterally to the femur, to meet the medial direction of this bone; the femora being directed medially here, to bring the knee-joints nearer the centre of gravity, and, so, counterbalance their wide separation above at the pelvis. The lateral pull of the quadriceps upon the patella is, in all normal action of the muscle, counteracted by the space taken in the trochlear surface by the lateral condyle, this being wider and creeping up higher, and having a more prominent and thus protective lip. In violent contraction, however, these counteracting points may be overcome.

The condyles of the femur and tibia.—It should be noted that on the medial side the prominence of the medial epicondyle of the femur is well marked, and that

FIG. 1165.—KNEE-JOINT AS SHOWN BY THE RÖNTGEN-RAYS, LATERAL VIEW.



of the tibia is less so, while on the lateral side this condition is reversed. Descending to the lateral condyle of the tibia, the ilio-tibial band of the fascia lata can be traced. The more distinct lateral condyle is a good landmark for opening the joint in amputation and excision. It also indicates the lower level of the synovial membrane of the knee-joint.

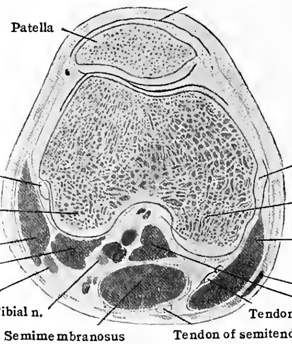
Farther back are the biceps and fibular collateral (long external lateral) ligament. The gap on the medial side between the femoral and tibial condyles is the place for feeling for a displaced medial fibro-cartilage in 'internal derangement' of the knee, and also for 'lipping' in suspected osteoarthritis. On each femoral epicondyle, posteriorly, in a thin subject, can be felt its tubercle, which gives attachment to the collateral ligament. Owing to their being placed behind the centre of the bone, these ligaments become tight in extension. On the upper and posterior part of the medial femoral epicondyle the adductor tubercle and the vertical tendon of the adductor magnus can be felt during flexion. This bony point is a guide to the lower epiphysis, the ossification of which and its occasional exostosis have been mentioned at p. 1442. The medial aspect of this epicondyle faces practically in the same direction as the head of the femur.

Ligamentum patellæ and tuberosity of tibia.—These, in a well-formed leg, should, with the centre of the ankle-joint, be all in the same straight line, a useful point in the adjustment of fractures. (Holden.) Behind the upper half of the ligament is the infrapatellar pad of fat; below, the lower half is separated from the tibia by a deep bursa. The tuberosity (tubercle) of the tibia is on a level with the head of the fibula.

Prepatellar bursa.—This usually protects the lower part of the patella and upper part of the ligamentum patellæ. It is liable to be enlarged in those who habitually kneel much, the enlargement being either fluid or solid, and occasionally, in tertiary syphilis. Its close connection with the patella and, at the sides, with the joint itself, is to be remembered in infective inflammations of the bursa. Usually the deep fascia, passing off from the sides of the patella upward to the thigh and downward to the leg, serves to conduct inflammation away from the joint.

Synovial membrane (fig. 1167).—This, the largest of the synovial membranes, forms a short *cul-de-sac* above the patella, between the quadriceps extensor and the front of the femur, this process reaching about 2.5 cm. (1 in.) above the trochlear surface of the femur. At its highest point this *cul-de-sac* communicates with an-

FIG. 1166.—HORIZONTAL SECTION OF THE KNEE-JOINT. (One-half.) (Braune.)



other synovial, bursa-like sac lying between the quadriceps and front of the femur. Thus, synovial membrane will usually be met with 6.2 cm. ($2\frac{1}{2}$ in.) or more above the trochlear surface or the upper border of the patella when the limb is extended. Flexing the joint draws the membrane down very slightly. During extension, the above pouch is supported by the articularis genu (subcrureus). Traced downward, the membrane reaches the level of the head of the tibia, being separated in the middle line from the upper part of the ligamentum patellæ by fat. It here gives off to the intercondyloid notch the patellar synovial fold (ligamentum mucosum), with its free lateral prolongations, the alar folds (ligamenta alaria). These three so-called ligaments contain fat, the processes not only padding gaps, but also meeting concussions.

The enlargement of these processes, under conditions not yet understood, may certainly be a cause of 'internal derangement,' and simulate a loosened meniscus. But the synovial membrane of this joint is not only the largest: it is also the most complicated, a fact accounting for the grave peril of infective arthritis, and the well-known difficulty of effective drainage and cleansing this joint. Thus 'it passes over the greater portion of the crucial ligaments, but the posterior surface of the posterior crucial, which is connected by means of fibro-areolar tissue to the front of the ligamentum posticum, and the lower portions of both crucial ligaments, where they are united together, of course cannot receive a complete covering from the membrane., (Morris.)

From the above ligaments the membrane is conducted, lining the lower part of the capsule and other ligaments, to the semilunar cartilages, first over their upper surfaces to their free borders, and then along their under surfaces to the tibia. Between the lateral of these and the upper and back part of the tibia is a prolongation of the synovial membrane to facilitate the play of the popliteus tendon.

Finally, amid the complications of this synovial membrane, its communication with some of the bursæ mentioned below, and occasionally with the superior tibio-fibular joint, is to be borne in mind. In effusion the bony prominences are obliterated, and the patella 'floats.' The knee-joint is easily opened by free lateral incisions lying midway between the margins of the patella and the tuberosities of the condyles, drainage-tubes being passed so as to meet above the patella. The above-mentioned complications of the synovial membrane show that such drainage will be often inadequate. By passing a director to the back of the joint and cutting down upon it carefully from the popliteal space, better drainage will be given, but opening the joint by an anterior flap is needed where the above fail, and, even then, cleansing of the numerous deep recesses is obviously difficult.

Structures on the head of the tibia.—From before backward these are:—(1) Transverse ligament. (2) Anterior end of medial meniscus (fibro-cartilage). (3) Lower attachment of anterior crucial. (4) Anterior end of lateral meniscus blending with (3). (5) Posterior extremity of lateral meniscus giving off a strong process to posterior crucial. (6) Posterior extremity of medial meniscus. (7) Posterior crucial ligament. *Menisci.*—These serve as buffer-bonds and cushions between the contiguous bones. The more frequent displacement of the medial is explained by—(*a*) its greater fixity, and, therefore, its feeling strains more. Thus, in addition to weaker attachments to the coronary and transverse ligaments, it is connected all along its convex border with the inside of the capsule, and strongly with the tibial collateral ligament. The lateral meniscus, on the other hand, is more weakly attached to the capsule, especially opposite to the popliteus tendon, and has no tie to the fibular collateral ligament. (*b*) When, in the erect position, the knee-joint is rotated laterally and slightly flexed, a common position, an especial strain is thrown upon the very important tibial collateral ligament, and from the above-mentioned connection, on the medial meniscus also.

Position of knee-joint in disease.—In inflammatory effusion, the position which best accommodates the collection of fluid is one of moderate flexion, the ligaments being now mainly relaxed. Later on, when the ligaments are softened, the hamstrings obstinately displace the leg backward, the tibia being rotated laterally by the biceps. The antero-posterior displacement is always more marked than the lateral. In straightening an anchylosed joint, the resistance of the shortened lateral, crucial, and posterior ligaments, and the facility with which a softened upper epiphysial line of the tibia may give way, must never be forgotten. **Erasion and excision.**—The extent and complications of the synovial membrane render attention to the following points imperative:—(1) Free exposure of the joint usually by an anterior curved incision, the medial extremity of which must not damage the great saphenous vein. (2) The extent of the pouch under the quadriceps, it may be for 5 cm. (2 in.) above the patella, and the lateral recesses under the vasti. The pouches at the back of the joint are far more difficult to deal with, viz., the partial covering of the posterior crucial ligament, the proximity of the popliteal artery, the pouches in relation to the popliteus, gastrocnemii, and back of the femoral condyles. In **erasion**, the cartilage and bone, where diseased, are removed with a gouge. Owing to the removal, in addition to the synovial membrane, of the fibro-cartilages, and crucial ligaments, and the damage to lateral and patellar ligaments, there is a most obstinate tendency to flexion afterward. In **excision**, to avoid injury to the epiphysis, the section of the femur should not pass higher than through the upper third of the trochlear surface. Of the tibia, only 12 mm. ($\frac{1}{2}$ in.) should be removed.

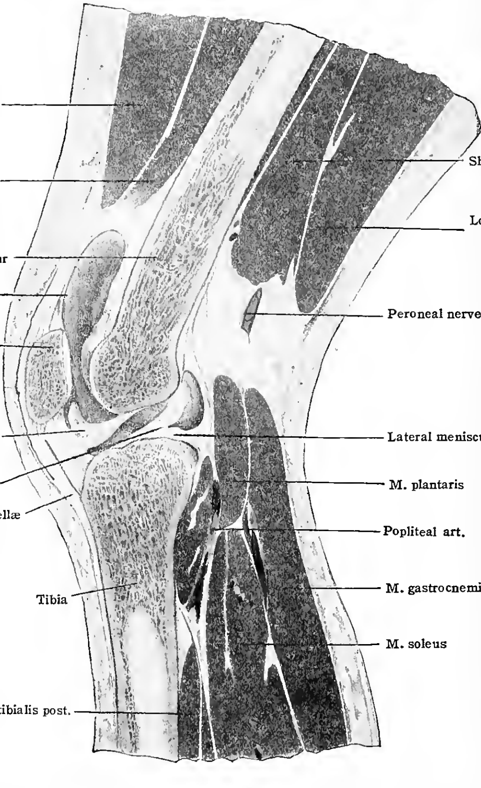
Genu valgum.—Here the natural angle at which the femur inclines medially to the tibia is increased. As shown by the late v. Mikulicz, this is due to an abnormal growth downward of the medial part of the femoral diaphysis, the epiphysial line being gradually altered from one at right angles to the shaft to one which runs obliquely from without downward and medially. The femur is not only elongated on its medial side, but bent at its lower end, the concavity of the curve being lateral. Other changes have to be remembered. Pes valgus very commonly coexists, and in the tibia there may be a compensatory curve, the concavity being medial, in the lower third, or an analogous alteration in the line of the upper epiphysis may be present, its direction being no longer at a right angle with the shaft, but oblique. In Sir W. Macewen's supra-condyloid osteotomy, a longitudinal incision, about 3.7 cm. ($1\frac{1}{2}$ in.) long is made where the following lines meet, viz., one transverse, a finger's breadth above the upper margin of the lateral condyle, and one longitudinal, 1.2 cm. ($\frac{1}{2}$ in.) in front of the adductor magnus tendon. The bone is divided in front of the genu suprema and above the superior medial articular artery, above the epiphysial line and behind the upward extension of the synovial membrane under the quadriceps.

The following **bursæ about the knee-joint** must be remembered. Some, it will be seen, are much more constant than others:—

A. **In front.**—(1) One between the patella and skin, the bursa prepatellaris subcutanea (fig. 1167); (2) a deeper one between the ligamentum patellæ and the upper part of the tibia; (3) between the skin and the lower part of the tuberosity of the tibia. This is not constant.

B. **On the medial side.**—(1) One between the medial head of the gastrocnemius and medial condyle, often extending between the above muscle and the semi-membranosus. This is the largest of the bursæ about the knee-joint, and, after adult life, usually communicates with the knee-joint. But, owing to the narrow communication, it is rarely possible, when the parts are relaxed by flexion of the joint, to empty the cyst. For its removal a straight incision is made over the most prominent part of the swelling, its neck found by drawing aside the tendons. A ligature is then pushed high up around the neck, and the cyst cut away. (2) One superficial to the tibial (collateral) ligament, between it and the tendon of the sartorius, gracilis, and semi

Fig. 1167.—Vertical Section of the Knee-joint in the Antero-posterior Direction. (The synovial bursa usually present above the upper synovial *cul-de-sac* is not shown.) (The bones are somewhat drawn apart.) (After Braune.)



tendinosus. (3) One beneath the ligament, between it and the tendon of the semi-membranosus. (4) One between the medial condyle of the tibia and the semi-membranosus. (5) One between the semi-membranosus and semi-tendinosus. Of the above bursæ, the first two alone are constant. The second and third are often one bursa prolonged.

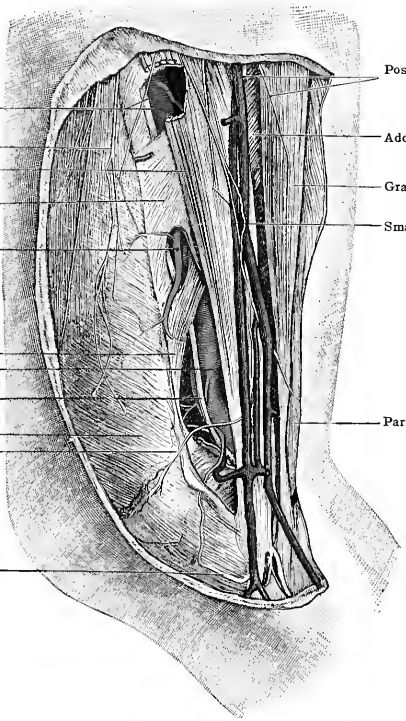
C. **On the lateral side.**—(1) One between the lateral head of the gastrocnemius and the condyle; (2) one superficial to the fibular collateral ligament between it and the biceps tendon; (3) one under the ligament between it and the popliteus tendon; (4) one between the popliteus tendon and the lateral condyle of the femur. This is usually a diverticulum from the synovial membrane.

The following explanations may be given of an inflamed knee-joint usually taking the flexed position:—(1) By experimental injections, Braune found that the capacity of the synovial sac reaches its maximum with a definite degree of flexion, i. e., at an angle of twenty-five degrees.

(2) As the same nerves supply the synovial membrane and the muscles which act upon the joint, reflex spasm of the flexors will help to explain the flexed position. (Hilton.)

Anastomoses around the front and sides of the knee-joint.—The most important of these take the form of **three transverse arches.** (1) The **highest** passes through the quadriceps fibres just above the upper edge of the patella. It is formed by a branch from the deep division of the genu suprema (anastomotica magna) and one from the lateral circumflex and superior lateral articular. The middle and lowest arches lie under the ligamentum patellæ. (2) The **middle arch,** formed by branches from the genu suprema and superior medial articular on the medial side, and the inferior lateral articular, on the lateral, runs in the fatty tissue

FIG. 1168.—SIDE VIEW OF THE POPLITEAL ARTERY.
(From a dissection in the Hunterian Museum.)



close to the apex of the patella. (3) The **lowest arch** lies on the tibia just above its tuberosity, and results from the anastomosis of the recurrent tibial and the inferior medial articular. Seven arteries thus take place in this series of anastomoses.

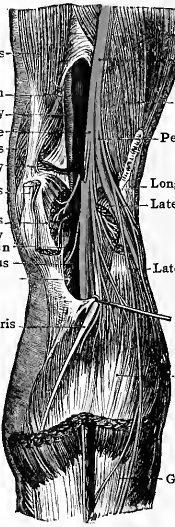
POPLITEAL SPACE

In flexion, the **hollow of this space** appears; in extension it is obliterated and its boundaries are ill-defined the only ones now to be made out being the semitendinosus and the biceps.

Popliteal tendons.—When the knee is a little bent and the foot rests on the ground, the following can be made out:—on the *lateral aspect*, behind the ilio-tibial band, and descending to the prominence on the lateral side of the head of the fibula, is the tendon of the biceps. This prominence also gives attachment to the fibular collateral ligament, which splits the tendon into two parts. Behind is the apex (styloid process) from which the posterior part of the fibular collateral ligament arises. Parallel and close to the medial border of the tendon, the peroneal nerve descends, as a rounded cord, to cross the neck of the fibula and enter the peroneus longus. In tenotomy of the biceps an open incision should be employed to avoid injury to the nerve and insure the division of any contracted fascial bands. On the *medial side* the tendons are thus arranged: Nearest to the middle of the popliteal space is the long and more slender tendon of the semi-tendinosus; next, the thicker tendon of the semi-membranosus; this and the gracilis, which comes next, appear as one tendon, but by a little manipulation the finger can be made to sink into the interval between the semi-membranosus, with its thick rounded border laterally and the gracilis medially. The sartorius can easily be thrown into relief on the medial side of the joint by telling the patient to raise the leg extended, the limb being rotated laterally and one leg crosses over the other.

Popliteal vessels.—The **artery** traverses this space from above downward, appearing beneath the semi-membranosus, a little to the medial side of the middle line, and then passing down in the centre of the space to the interval between the gastrocnemii. Its course corresponds with a line drawn from the medial side of the

Fig. 1169.—Deep View of the Popliteal Space. (Hirschfeld and Leveillé.)



hamstrings to the centre of the lower part of the space. The artery bifurcates on the level of a line corresponding to the tuberosity of the tibia. It lies on the popliteal surface of the femur, the oblique popliteal ligament and the popliteus. It is the second of these structures which usually prevents popliteal aneurism and abscess from making their way into the joint.

The **popliteal vein,** intimately adherent to the artery, lies to the lateral side above, but crosses to its medial side below. The popliteal sheath is also unusually strong. The **tibial nerve** crosses the artery in the same direction as the vein, by which it is separated from the artery. This nerve is the direct continuation of the sciatic nerve (fig. 1169), and enters more into the space than its fellow branch. The close relation of the vein and nerve explains the early stiffness of the knee, the pains below, often called 'rheumatic,' and the œdema, in popliteal aneurism; also the pulsation of swellings not aneurismal.

The **superior articular arteries** (fig. 1169) course laterally and medially immediately above the femoral condyles; the way in which they cling closely to the bone here is one provision to prevent overstretching of the artery; the **inferior** ones lie just above the head of the fibula and below the medial condyle of the tibia (fig. 1169). The deep part of the genu suprema artery runs in front of the tendon of the adductor magnus; the superficial with the saphenous nerve.

The **popliteal artery may be ligatured**—(A) **Behind,** in the upper part of the popliteal space, just after its emergence from under the semi-membranosus. Here, for a short space of about 2.5 cm. (1 in.), the vessel is comparatively superficial after division of the fasciæ. The nerve is generally seen first, and, with the vein, must be drawn laterally. The needle should be passed from the vein. (B) **From the front,** at the medial side. The thigh being flexed, abducted, and rotated laterally, a free incision is made parallel and just behind the adductor magnus tendon, commencing at the junction of the middle and lower third of the thigh. The sartorius and the hamstrings are drawn backward, and the adductor magnus forward. Care must be taken of the genu suprema (fig. 1168). The space between the hamstrings and the adductor magnus being carefully opened up, the artery will be found in fatty areolar tissue. The vein and tibial nerve are on the lateral side of the vessel. The needle is passed in lateromedially. The collateral circulation (fig. 1156) depends chiefly on the genu suprema.

The **small saphenous vein** perforates the roof of the popliteal space in its lower part. As a rule, it is not visible, unless enlarged.

The **popliteal nodes** are not to be felt unless enlarged.

Bursæ in the popliteal space.—These have been already spoken of (p. 1449).

THE LEG

The skin.—The proneness of the skin to dermatitis in the lower third of the medial and front aspect of the leg as a result of varicose veins is well known. The close contiguity of the periosteum to the skin here accounts for the difficulty in healing chronic ulcers whose callous base has become fixed to the periosteum, and the frequency with which the upper fragment of a fractured tibia perforates the skin.

Bony landmarks.—From the *tuberosity* (tubercle) *of the tibia* descends the *anterior border* or 'shin.' This soon becomes sharp, and continues so for its upper two-thirds; in the lower third it disappears, to be overlaid by the extensor tendons. It is curved somewhat laterally above and medially below. The *medial border* can also be felt from the medial condyle to the medial malleolus. Between these two borders lies the *medial surface,* subcutaneous save above, where it is covered by the three tendons of insertion of the gracilis and semi-tendinosus, and, overlying them, that of the sartorius. The tibia is narrowest and weakest at the junction of the middle and lower thirds, the most common site of fracture. Behind the *medial malleolus,* part of the groove for and the tendon of the tibialis posterior can be felt.

The *head of the fibula* can be felt distinctly, but the shaft soon becomes buried amongst muscles till about 7.5 cm. (3 in.) above the *lateral malleolus,* where the bone expands into a large triangular subcutaneous surface.

This lies between the peroneus tertius and the other two peronei. The peroneus longus overlaps the brevis, especially in the upper two-thirds of the leg. In the lower third the brevis tends to become anterior (fig. 1173). Behind the lateral malleolus these tendons descend to the foot in a groove on its posterior border. The shaft of the fibula is placed on a plane posterior to that of the tibia, and curves backward in a direction reverse to that of the tibia.

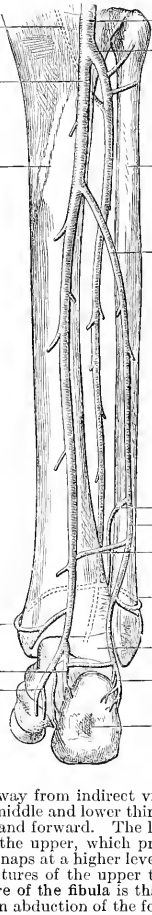
Muscular compartments and prominences.—When the muscles of the leg are thrown into action by dorsi-flexion and plantar flexion of the foot or by standing on the toes, several groups of muscles stand out on the surface, owing to certain **compartments,** and the origin of certain muscles from, and their separation by, the deep fascia, which knits the surface into corresponding elevations and depressions. The bones and the two peroneal septa divide the leg into four **compartments.**

These are, medio-laterally:—(1) A **medial,** corresponding to the medial surface of the tibia. (2) An **anterior,** between the crest of the tibia and the anterior peroneal septum, attached to the antero-lateral border of the fibula, and separating the extensors from the peronei. Its surface-marking would be a line from the front of the head of the fibula to the front of the lateral malleolus. In this anterior compartment lie the extensor muscles and origin of the peroneus tertius, and the anterior tibial vessels and nerves. (3) A **lateral** or **peroneal** compartment, lying between the anterior and posterior peroneal septum, the latter being attached to the postero-lateral border of the fibula, and separating the peronei from the calf and deep flexors. This peroneal compartment, a narrow one, contains the two chief peronei and the peroneal (external popliteal) nerve and its three divisions. (4) Much the largest, this, the **posterior,** lies between the posterior peroneal septum and the medial border of the tibia, and contains the calf and deep flexor muscles, the posterior tibial vessels and nerves, and the peroneal artery and its posterior branch.

The space between the tibia and fibula in front is mainly occupied by the fleshy belly of the tibialis anterior; lateral to this, and much less prominent, is the narrower extensor digitorum longus; lateral to this, again, are the peronei longus and brevis. Lower down, in an interval between the tibialis and the extensor of the toes, the extensor hallucis, here almost entirely tendinous, comes to the surface. Behind, the prominence of the calf is mainly formed by the gastrocnemius. On the patient's rising on tip-toe, the tendo Achillis starts into relief from about the middle of the leg. Of the two heads of the gastrocnemius, the medial is seen to be the larger. On either side of the tendon, but more distinctly on the lateral side, where it is less overlapped by the gastrocnemius, the soleus comes into view. Its muscular fibres are continued on the deep surface of the tendon to within a short distance of the heel. Between the tendon and the upper part of the os calcis is a bursa, occasionally the seat of effusion, as in gonorrhœa.

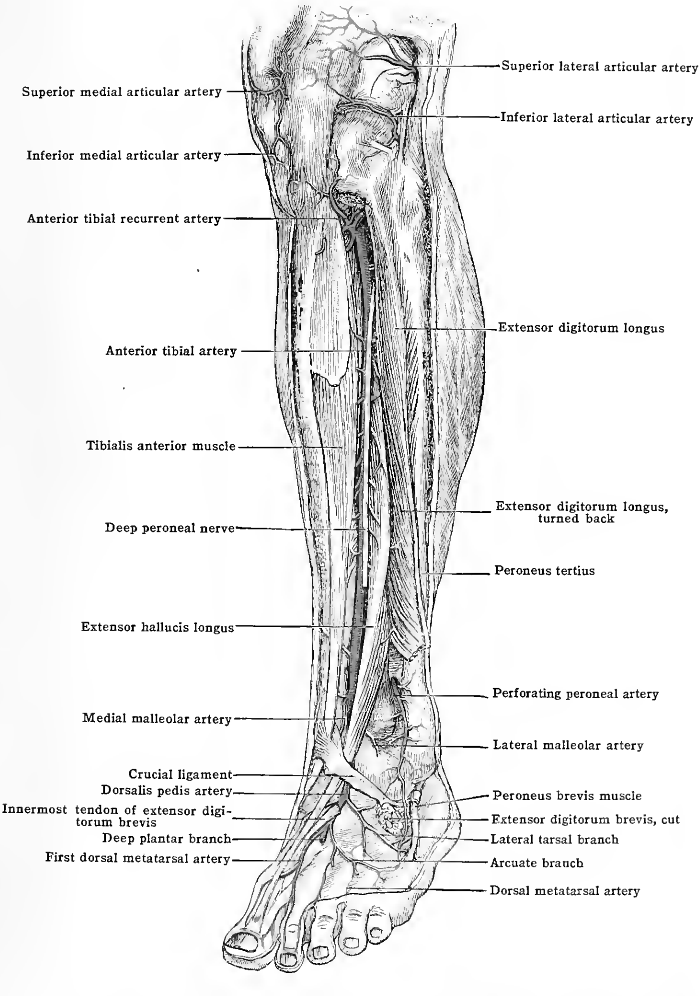
The bones.—Their relative position and curves have been mentioned (p. 1453). **Access.**—That to the **tibia** is easy along the medial aspect. The **fibula** is best explored by a free incision along the line of the posterior peroneal septum, which lies between the peronei and the muscles at the back (p. 1453). The presence of the superficial peroneal (musculo-cutaneous) nerve perforating the deep fascia in the lower third below and that of the common peroneal (external popliteal) in relation to the neck of the fibula above, must be remembered. **Fractures.**—When,

Fig. 1170.—Anastomoses of Tibial Arteries.



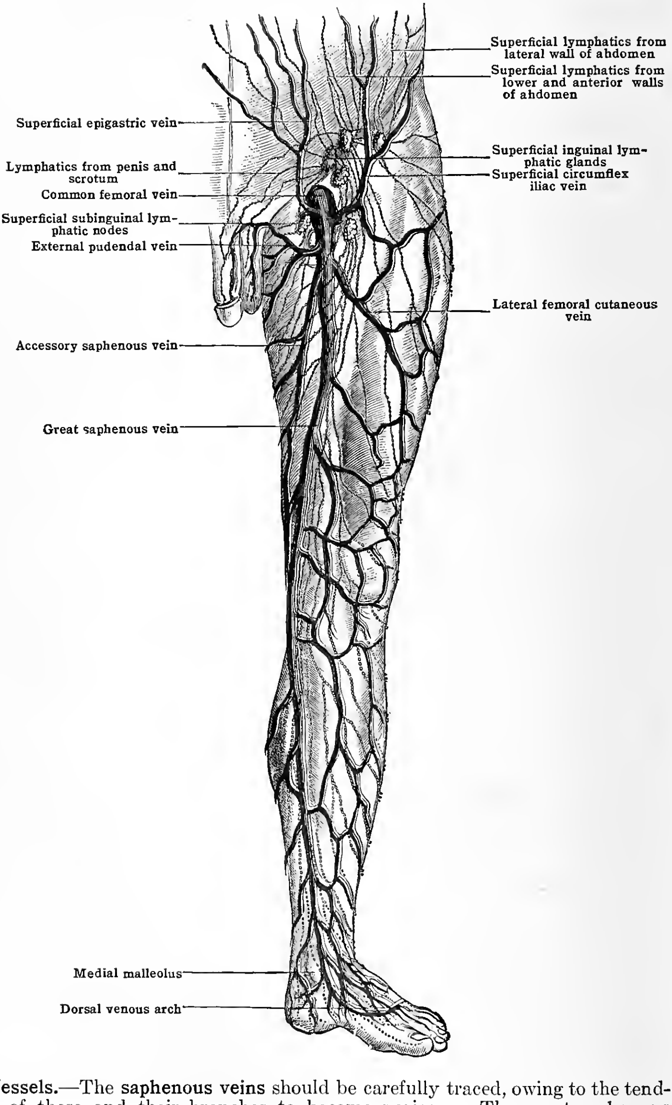
as is most frequent, the tibia gives way from indirect violence, the fracture is usually at the weakest spot, or the junction of the middle and lower thirds. The line of obliquity is generally marked, and from above downward and forward. The lower fragment, pulled upward by the powerful calf muscles, rides behind the upper, which projects forward under the skin. The fibula, bending more than the tibia, snaps at a higher level. Tenderness on pressure is the best guide here, as it is in suspected fractures of the upper tibia, transverse from direct violence. The most common variety of **fracture of the fibula** is that called after **Pott,** complicated with displacement of the foot. Here, from abduction of the foot, a severe strain is thrown upon the deltoid ligament, which gives way; the talus (astragalus) is pressed against the lateral malleolus, and the inferior tibio-fibular ligaments resisting, the fibula yields 5 to 7 cm. (2 to 3 in.) above the ankle, the upper end of the lower fragment being usually displaced toward the tibia. If the deltoid ligament is strong, the strain often tears off the medial malleolus. The medial margin of the foot is turned toward the ground, the lateral raised. The foot is also displaced backward. On the medial side of the ankle there is a marked projection of the lower end of the tibia; higher up, on the lateral side, a depression where the fibula is broken. The need of replacing the foot and the weight-bearing talus (astragalus) accurately, the fact that the ankle-joint is opened and the numerous tendons likely to be matted are the chief points to bear in mind. In **Dupuytren's fracture** there is not only fracture of the lower end of the fibula, but the inferior tibio-fibular ligaments are now torn. The foot is displaced upward and laterally, together with the lower

Fig. 1171.—The Anterior Tibial Artery, Dorsal Artery of the Foot, and Perforating Branch of the Peroneal Artery, and Their Branches.



end of the fibula. **Epiphyses.**—The upper one of the tibia appears shortly before birth and includes the condyle and tuberosity. It does not fuse with the shaft till the age of twenty or later. This fact and the powerful strain of the rectus on this epiphysis explain the obscure pain sometimes complained of in young adults much given to athletics, over the tibial tuberosity. The lower epiphysis, including the medial malleolus, appears in the second and joins about the eighteenth year. Separation here is not very uncommon up to puberty. In **osteotomy** of the tibia, simple or cuneiform, when the curve is antero-posterior as well as lateral, the close vicinity of the tibialis anterior tendon to the lateral border of the crest must be remembered, and when the fibula does not yield to careful force, it, also, must be divided, or damage may be done to the superior and inferior tibio-fibular ligaments, or to the epiphyses of the bones.

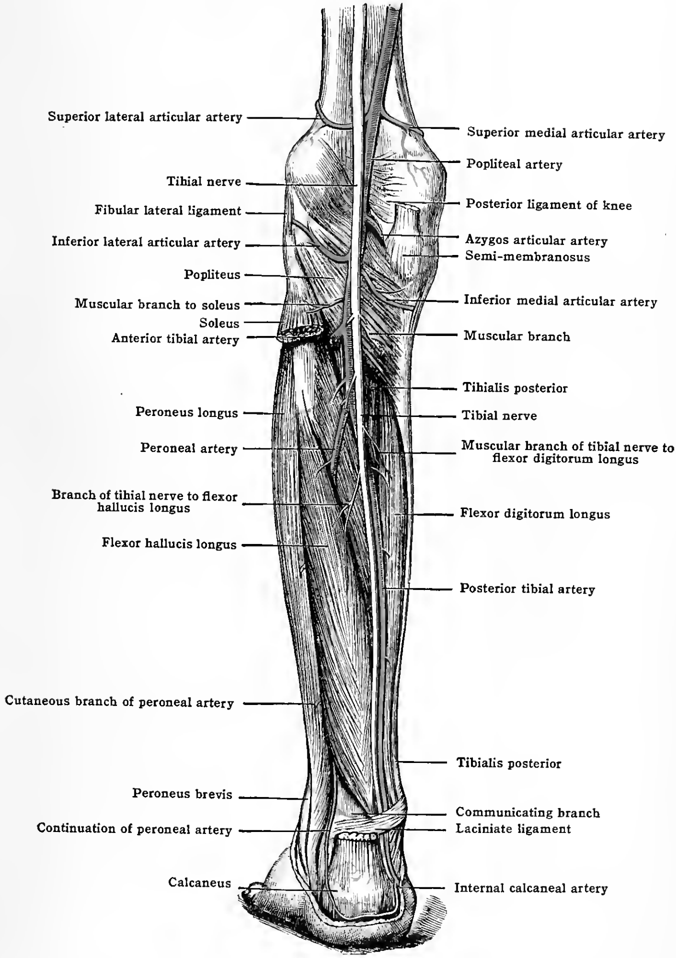
Fig. 1172.—The Superficial Veins and Lymphatics of the Left Lower Limb.



Vessels.—The **saphenous veins** should be carefully traced, owing to the tendency of these and their branches to become varicose. The **great saphenous**

(figs. 1158, 1172), having passed from the arch on the dorsum over the medial malleolus, runs up close to the medial border of the tibia, where it is to be avoided in ligature of the posterior tibial, to the back of the medial condyle; here this vessel is to be remembered in operations on the knee-joint; then upward along the thigh, over the roof of the adductor (Hunter's) canal, to the fossa ovalis (saphe-

Fig. 1173.—Relations of the Popliteal Artery to Bones and Muscles.



nous opening) (p. 1440 and fig. 1172), where it joins the femoral by perforating the cribriform fascia and the femoral sheath. Four to six valves are present, chiefly in the upper part.

The 'dangerous area,' or that in which thrombosis is most likely to occur, reaches from the centre of the thigh to the middle of the leg. (Bennett.) The saphenous nerve joins the vein below the knee, having been under the sartorius above this point (fig. 1159 and 1160). The surface-marking of the upper part of the vein is a line drawn from the posterior border of the sartorius or the adductor tubercle to the lower part of the fossa ovalis. The **small saphenous** vein passes behind the lateral malleolus, runs upward over the middle of the calf, and joins the popliteal by perforating the deep fascia in the lower part of the popliteal space. This vein is accompained by the medial sural cutaneous (external saphenous) nerve throughout its course.

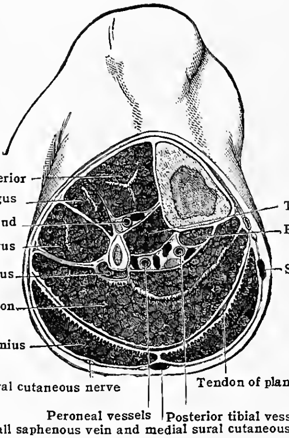
The **popliteal artery** bifurcates at the lower border of the popliteus, about on a level with the tuberosity of the tibia. About 5 cm. (2 in.) lower down the peroneal artery comes off from the posterior tibial (fig. 1173).

The course of the **posterior tibial** corresponds with a line drawn from the centre of the lower part of the popliteal space to a point midway between the tip of the medial malleolus and the medial edge of the calcaneus.

In the lower third, the artery becomes more superficial, passing from beneath the calf muscles, lying between the tendo Achillis and medial border of the tibia, and covered only by the skin, deep fascia, and, lower down, by the laciniate (internal annular) ligament. It is here, in its close relation to the tendons of the tibialis posterior and flexor digitorum longus, that it is liable to be injured in the older methods of tenotomy. The nerve is medial above, lateral below (fig. 1173).

Ligature of the posterior tibial in the middle of the leg.—The following are the chief points in the technique. An incision, 7.5 to 10 cm. (3 to 4 in.) long, is made 1.2 cm. (½ in.) behind the

Fig. 1174.—Upper Segment of a Section of the Right Leg in the Upper Third. (Heath.)



medial_border of the tibia, to avoid the trunk of the great saphenous. The deep fascia being freely opened, the medial head of the gastrocnemius is drawn backward. The tibial attachment of the soleus, thus exposed, is cut through carefully, so as to allow of identification of its central membranous tendon, which must not be confused with the deep intermuscular septum over the flexor. Any sural vessels are now tied. The above-mentioned special septum is next made out, passing between the bones (vertical line descending from oblique line of tibia and oblique line of fibula). On division of this septum the nerve usually comes into view, the artery lying more laterally. The needle is passed from the nerve; the venæ comitantes may be included. The muscles should now be fully relaxed by flexion of knee and plantar flexion of foot. The ligature will be placed below the peroneal artery.

The course of the **anterior tibial artery** corresponds with a line drawn from a point midway between the lateral condyle of the head of the tibia and the head of the fibula to one on the centre of the ankle-joint.

This line corresponds to the lateral border of the tibialis anterior and the interval between it and the extensor digitorum longus (figs. 1170 and 1171). This is shown when the first of these muscles is thrown into action. The accompanying nerve is in front in the middle third of the leg, lateral above and below.

Ligature of the anterior tibial artery at the junction of the upper and middle thirds of the leg. The limb being flexed and rotated medially, an incision is made, 7.5 to 10 cm. (3 to 4 in.) long, in the line of the artery, distant 2.5 cm. (1 in.) or more (according to the size of the leg) from the crest, and beginning about 5 cm. (2 in.) below the head of the tibia. If, on exposure of the deep fascia, the intermuscular septum between the tibialis and long extensor of the toes is not well defined, the fascia must be freely slit up in the line of the artery, and the sulcus felt for. A small muscular artery may lead down to the trunk. The foot is now dorsiflexed and the artery sought for deep on the interosseous membrane. The nerve should be drawn to the outer side. The venæ comitantes may be included in the ligature.

In **senile gangrene** the liability of the tibial arteries to disease and consequent thrombosis and interference with the collateral circulation accounts both for the extension of the disease and the difficulty in detecting pulsation.

The **peroneal artery,** given off from the posterior tibial about an inch below the popliteus, or two inches below the head of the fibula, runs deeply along the medial border of this bone, covered by the flexor hallucis longus, the nerve to which accompanies the vessel.

It gives off the *anterior peroneal,* through the interosseous membrane, to the front of the lateral malleolus about an inch above the level of the ankle-joint. Its continuation, as the posterior peroneal, runs behind the malleolus, to join the anastomosis about the ankle-joint.

The **nutrient artery** of the tibia arises from the posterior tibial near its commencement. It is the largest of all the nutrient arteries to the shafts of long bones; that for the fibula comes from the peroneal.

As a general rule, in **amputation** 2.5 cm. (1 in.) below the head of the fibula, only one main artery—the popliteal—is divided. In amputations 5 cm. (2 in.) below the head of the fibula, two main arteries—the anterior and posterior tibials—are divided. In amputations 7.5 cm. (3 in.) below the head, three main arteries—the two tibials and the peroneal—are divided. (Holden.)

In an amputation through the middle of the leg, the anterior tibial artery would be found cut on the interosseous membrane between the tibialis anterior and the extensor hallucis longus, the deep peroneal nerve here lying in front of the vessel. The posterior tibial would be between the superficial and deep muscles at the back of the leg lying on the tibialis posterior, its nerve being to the lateral side. The peroneal would be close to the fibula in the flexor hallucis longus.

The **superficial peroneal** (musculo-cutaneous) nerve, having passed through the peroneus longus and then between the peroneus longus and peroneus brevis, perforates the deep fascia in the lower third of the leg in the line of the septum between the peronei and extensors. Directly after, it divides into its two terminal branches.

Amputation of the leg.—To give one instance only, amputation 'at the seat of election, or a hand's-breadth below the knee-joint, will be alluded to. Lateral skin-flaps and circular division of the muscles give an excellent result in hospital practice where the various conditions which call for such a step are usually met with. The above name was given because the pressure of the body is well carried on the prominences about the knee-joint, especially the tuberosity of the tibia, when the patient walks with the knee flexed on a 'bucket' artificial limb. Thus the scar, being central, is here not of importance. Two broadly oval lateral flaps of skin and fasciæ are raised, and the remaining soft parts severed down to the bones with circular sweeps of the knife. In sawing the bone, the smaller size of the fibula and its position behind the tibia must be remembered. It is well, in order to ensure complete division of the fibula first, to roll the limb well over on its medial side, and place the saw well down on the lateral side. The parts cut through are shown in fig. 1174.

THE ANKLE

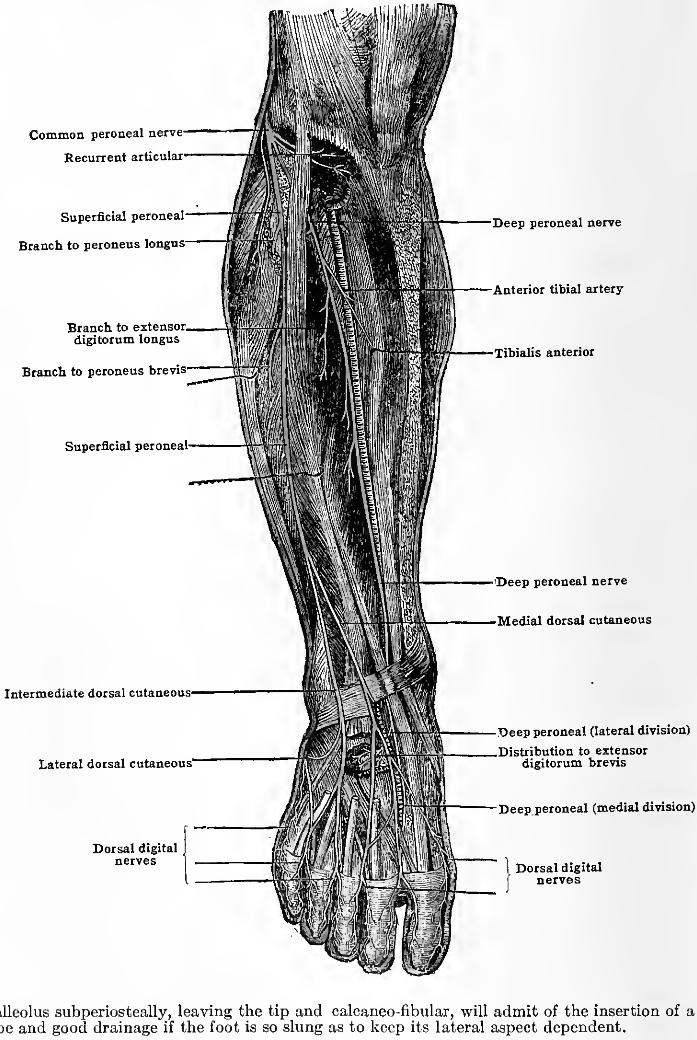
Bony landmarks.—The following are the differences between the two **malleoli:** The **medial** is the more prominent, shorter, and is placed more anteriorly than the lateral, being a little in front of the centre of the joint. The **lateral** descends lower by about 1.2 cm. (½ in.), and thus securely locks in the joint on this side; it is opposite to the centre of the ankle-joint, being placed about 1.2 cm. (½ in.) behind its fellow.

Owing to the lateral malleolus descending lower than the medial, in Syme's and Pirogoff's amputations the plantar incision should run between the tip of the lateral malleolus and a point 1.2 cm. (½ in.) below that of the medial one. When a fracture is set, or a dislocation adjusted, the medial edge of the patella, the medial malleolus, and the medial side of the great toe are useful landmarks and should be in the same vertical plane, regard being paid at the same time to the corresponding points in the opposite limb. (Holden.)

On the posterior aspect of the medial malleolus is a groove for the tibialis posterior and flexor digitorum longus, the first named being next the bone. The tip and borders of the process give attachment to the deltoid ligament. The anterior border and tip of the lateral malleolus give attachment to the anterior talo-fibular and calcaneo-fibular ligaments respectively, the posterior talo-fibular arising from a pit behind and below the articular facet. The posterior border is grooved for the two peronei. The line of the ankle-joint corresponds to one about 1.2 cm. (½ in.) below the tip of the medial malleolus drawn across the anterior aspect.

Effusion or tuberculous thickening shows itself first in front, between the medial malleolus and tibialis anterior and between the peroneus tertius and lateral malleolus and then behind, where it fills up the hollow between the tendo Achillis and the two malleoli. Owing to the thinness of the transverse crural (anterior) ligament, the extensor sheaths are easily affected in neglected tuberculous disease. Owing to the way in which the joint is locked in, it is not easy to open and drain an infected ankle-joint satisfactorily. Removal of a portion of the lateral

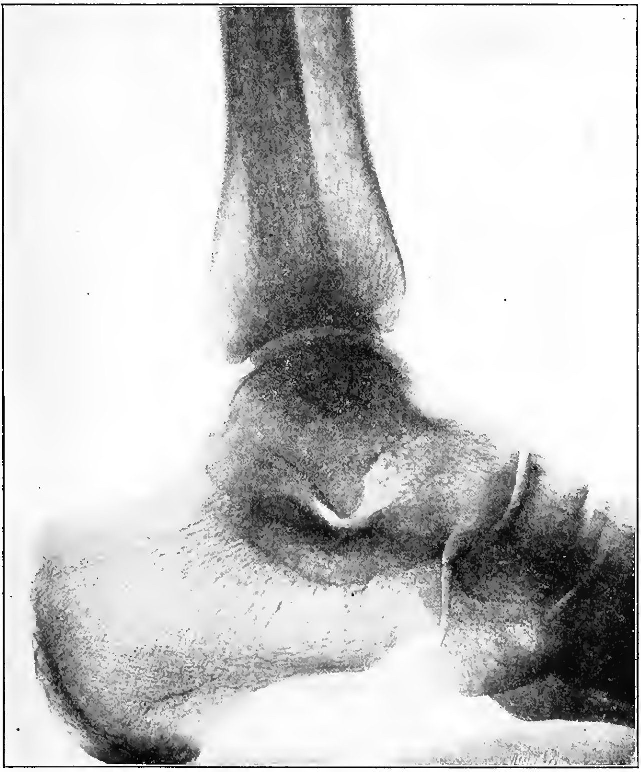
FIG. 1175.—BRANCHES OF THE COMMON PERONEAL NERVE.



malleolus subperiosteally, leaving the tip and calcaneo-fibular, will admit of the insertion of a tube and good drainage if the foot is so slung as to keep its lateral aspect dependent.

Tendons.—(A) **In front of ankle.**—Latero-medially are—(1) The tibialis anterior, the largest and most medial. This tendon appears in the lower third of the leg, lying just under the deep fascia, close to the tibia; then, crossing over the lower end of this and the ankle-joint, it passes over the medial side of the tarsus, to be inserted into the medial and lower part of the first cuneiform and the adjacent part of the first metatarsal. (2) The extensor hallucis longus. This tendon, concealed above, appears low down in a line just lateral to the last, and then, crossing over the termination of the anterior tibial vessels and nerves (to which its muscular part lies lateral), it descends along the medial part of the dorsum to be inserted into the base of the last phalanx of the great toe. (3) and (4) The extensor digitorum longus and peroneus tertius enter a common sheath in the transverse crural ligament. The former then divides into four tendons, which

FIG. 1176.—LATERAL VIEW OF THE ANKLE REGION, AS SHOWN BY THE RÖNTGEN-RAYS

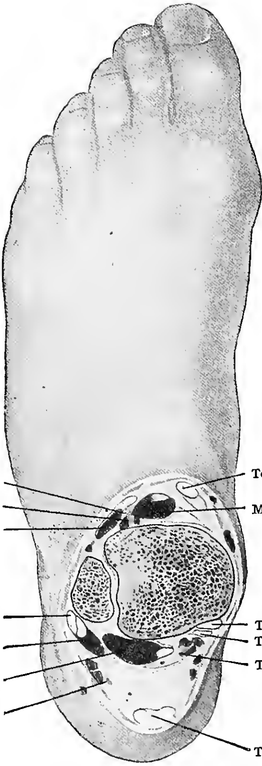


run to the four lateral toes. The peroneus tertius is inserted into the upper surface of the base of the fifth (often also the fourth) metatarsal bone.

(B) **Behind.**—The tendo Achillis, the thickest of all tendons, begins near the middle of the leg, in the junction of the tendons of the gastrocnemii and, a little lower, (p. 1453) the soleus. Very broad at its commencement, it gradually narrows and becomes very thick. About 3.7 cm. ($1\frac{1}{2}$ in.) from the heel, or about the level of the medial malleolus, is its narrowest point. After this it again expands slightly, to be inserted into the middle of the back part of the calcaneus. The long tendon of the plantaris runs along its medial side, to blend with it or to be attached to the calcaneus. On either side of the tendo Achillis are well-marked furrows below. Along the medial, the tendon of the tibialis posterior and the posterior tibial vessels and nerve come nearer the surface. Along the lateral, the small saphenous vein (more superficially) ascends from behind the lateral malleolus.

(C) **On the medial side.**—The tendon of the tibialis posterior, which has previously crossed from the interspace between the bones of the leg to the medial side, lies behind the inner edge of the tibia above the medial malleolus, then behind this, being here under the flexor digitorum longus, the two tendons having become superficial on the medial side of the tendo Achillis. It then passes forward over the deltoid and under the laciniate (internal annular) ligament between the medial malleolus and the sustentaculum tali, and then below and close to the plantar cal-

FIG. 1177.—HORIZONTAL SECTION THROUGH THE LOWER PART OF THE LEG. (After Braune.)



caneo-navicular ligament (*vide infra*), and so to its insertion, by numerous slips, into the tarsus and metatarsus, especially the tuberosity of the navicular. The tendon of the flexor hallucis longus cannot be felt. Having passed medially from the fibula, it crosses the lower end of the tibia in a separate furrow, then grooves the backof the talus, and passes under the sustentaculum tali on its way to its insertion.

The arrangement of the structures at the medial ankle from above downward, and mediolaterally, is as follows (fig. 1177):—tibialis posterior, flexor digitorum longus, companion vein, posterior tibial artery, companion vein, tibial nerve, flexor hallucis longus. The tibiales posterior and anterior turn the sole medially, antagonising the peronei. They also bear a large share in maintaining the longitudinal arch of the foot. The flexors not only act upon the toes, but aid the calf muscles in straightening the foot upon the leg in walking or standing upon tiptoe; hence the value of educating them in cases of flat-foot.

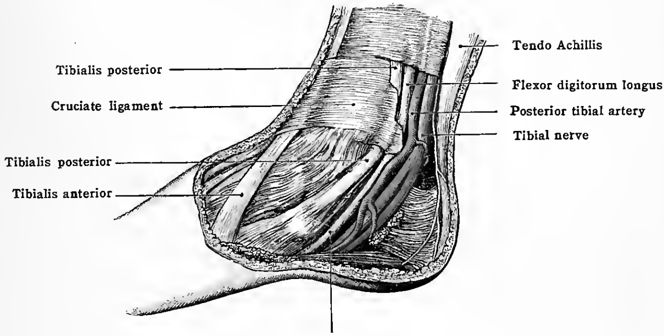
(D) **Tendons on the lateral aspect.**—The tendons of the two peronei, which arise from the fibula between the extensor digitorum longus and flexor hallucis longus, pass behind the lateral malleolus, the brevis being nearer to the bone (fig. 1177). They then pass forward over the lateral surface of the calcaneus, separated by the peroneal tubercle when present, and diverge.

The brevis—the upper one—passes to the projection at the base of the fifth metatarsal; the longus, lying below the brevis on the calcaneus, winds round the lateral border of the foot, grooving the lateral border and under surface of the cuboid. Finally, crossing the sole obliquely forward and medially, it is inserted into the adjacent parts of the first cuneiform and the back part and under surface of the first metatarsal. While in connection with the under surface of the cuboid, this tendon is covered in by a sheath from the long plantar ligament, and often contains a sesamoid bone. The two peronei evert the foot, as is seen in talipes valgus and in fracture of the lower end of the fibula; the peroneus longus aids in the support of the arch of the foot (p. 1466), and, by keeping the great toe on the ground, is important in the third stage of walking, skating, etc.

Annular ligaments and synovial membranes of tendons.—These strap-like bands of deep fascia, which serve to keep the above tendons in position, are three in number, viz.:—

(A) **Lateral.**—This, the superior peroneal retinaculum, extends from the tip of the lateral malleolus to the lateral surface of the calcaneus. It keeps the two

Fig. 1178.—Relations of Parts behind the Medial Malleolus. (Heath.)



peronei in place, and surrounds them behind the fibula in one sheath with a single synovial sac, which extends upward into the leg for 3.7 cm. ($1\frac{1}{2}$ in.), and sends two processes into the two sheaths in which the tendons lie on the calcaneus. Farther on, while in relation with the cuboid, the peroneus longus has a second synovial sheath.

(B) **Medial.**—This, the laciniate ligament, crosses from the medial malleolus to the medial surface of the calcaneus. Beneath it are the following canals:—(1) For the tibialis posterior. This tendon-sheath is lined by a synovial membrane extending from a point 3.7 cm. ($1\frac{1}{2}$ in.) above the malleolus to the navicular. (2) For the flexor digitorum longus. The synovial sheath of this tendon is separate from that of the closely contiguous tibialis posterior. It extends upward into the leg about as high as the sheath just given. It reaches down into the sole of the foot; but where the tendon subdivides to enter the thecæ, each of these is lined by a separate synovial sheath. Next comes (3) a wide space for the posterior tibial vessels and nerve; and, lastly, (4) a canal, like the other two, with a separate synovial sheath, for the tendon of the flexor hallucis longus. The lower margin of this annular ligament gives an attachment to the abductor hallucis and blends with the plantar fascia. The medial calcaneal vessels and nerve perforate the ligament.

(C) **Anterior annular ligament.**—This is a double structure. (1) **Upper (transverse crural ligament), above the level of the ankle-joint,** and tying the tendons down to the lower third of the leg, passes transversely between the anterior crest of the tibia and fibula. Here is one sheath only, with a synovial membrane for the tibialis anterior. (2) **Lower, over the ankle-joint.** This band, the **cruciate ligament,** is arranged like the letter ≺, placed thus. It is attached by its root to the calcaneus, and by its bifurcations to the medial malleolus and plantar fascia.

This arrangement of the branches of this ligament is not constant. In this, the lower annular ligament, there are usually three sheaths with separate synovial membranes—the most medial (the strongest in each) for the tibialis anterior, the next for the extensor hallucis longus, and the third common to the extensor communis and peroneus tertius. The extensor digitorum brevis has a partial origin from this ligament.

Points in tenotomy and guides to the tendons.—The tendo **Achillis** should be divided about 3.7 cm. ($1\frac{1}{2}$ in.) above its insertion, its narrowest point, which is about on a level with the medial malleolus. The knife should be introduced on the medial side and close to the tendon, so as to avoid the posterior tibial artery (fig. 1178).

The **tibialis anterior** may be divided about 25 mm. (1 in.) above its insertion into the first cuneiform, a point which is below the level of its synovial sheath. The tendon has here the dorsalis pedis on its lateral side, but separated by the tendon of the extensor hallucis longus. The knife is introduced on this side.

The **tibialis posterior.**—The usual rule for dividing this tendon is to take a spot 5 cm. (2 in.) above the medial malleolus, and as accurately as possible midway between the anterior and medial borders of the leg. This point will give the medial margin of the tibia, in close apposition to which the tendon is lying, and is a point at which the tendon is rather farther from the artery than it is below, and is also above the commencement of its synovial sheath. A sharp-pointed knife is used first to open the sheath freely, and then a blunt-pointed one to divide the tendon. The flexor digitorum longus is usually cut at the same time.

Owing to the risk of injury to the posterior tibial vessels, the difficulty of ensuring division of the tendons, the following open method is, nowadays, superior, being more certain, and admitting of division of ligaments, e. g., talo-navicular and anterior part of deltoid (syndesmotomy of Parker), which are always contracted in advanced talipes equino-varus. A **V**-shaped flap with its apex over the first metatarsal bone, and its two limbs starting, the lower below the margin of the plantar fascia on a line with the medial malleolus, the upper from a point over the head of the talus, is turned backward. The plantar fascia is divided, the tibialis anterior is found, near its insertion, under the upper lip of the wound, the tibialis posterior and the flexor digitorum longus in the lower, the former close to the navicular. If necessary, the calcaneo- and talo-navicular and anterior part of the deltoid ligaments can be divided also.

Peronei.—The peronei longus and brevis may be divided 5 cm. (2 in.) above the lateral malleolus, so as to be above the level of their synovial sheath. The knife should be inserted very close to the bone, so as to pass between the fibula and the tendons. Division below the ateral malleolus by a small flap is easier.

THE FOOT

Bony landmarks.—The following are of the greatest practical importance owing to the operations which are performed upon the foot.

(A) **Along the medial aspect of the foot** are the following:—

(1) Medial tuberosity of the calcaneus; (2) medial malleolus; (3) 2.5 cm. (1 in.) below the malleolus, the sustentaculum tali; (4) about 2.5 cm. (1 in.) in front of the medial malleolus, and a little lower, is the tuberosity of the navicular, the medial guide in Chopart's amputation, the gap between it and the sustentaculum being filled by the calcaneo-navicular ligament and the tendon of the tibialis posterior, in which there is often a sesamoid bone; (5) the first cuneiform; (6) the base of the first metatarsal; and (7) the head of the same bone, with its sesamoid bones below. (Holden).

(B) **Along the lateral aspect** are:—(1) The lateral tuberosity of the calcaneus; (2) the lateral malleolus; (3) the peroneal tubercle of the calcaneus (when present), 2.5 cm. (1 in.) below the malleolus, with the long peroneal tendon below it, and the short one above; (4) the projection of the anterior end of the calcaneus, and the calcaneo-cuboid joint, midway between the tip of the lateral malleolus and the base of the fifth metatarsal bone; (5) the base of the fifth metatarsal bone; (6) the head of this bone. The greater process of the calcaneus and the muscular origin of the short extensor lie between the peroneus brevis and tertius.

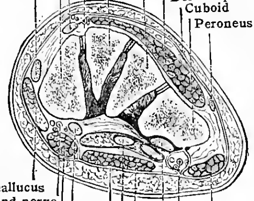
Levels of joints and lines of operations.—The line of the ankle-joint has been given at p. 1459. That of the talo-calcaneal joint—the limited lateral movements of the foot take place here and at the medio-tarsal joint—corresponds, on the lateral side, to a point a little in front of the lateral malleolus and midway between it and the peroneal tubercle; on the medial side, to one just above the sustentaculum tali. In **Syme's amputation** through the ankle-joint, the incision starts from the tip of the lateral malleolus, and is then carried, pointing a little backward toward the heel, across the sole to a point 1.2 cm. (½ in.) below the medial malleolus. The chief supply to the heel-flap is from the medial calcaneal. Care should be taken to divide the posterior tibial below its bifurcation and not to prick this vessel afterward.

In **Pirogoff's amputation** the incision begins and ends at the same points, but is carried straight across the sole. In each amputation the extremities of the above incision are joined by one going directly across the ankle-joint, which lies about 1.2 cm. (½ in.) above the tip of the internal malleolus.

In **Chopart's medio-tarsal amputation,** which passes between the talus and the navicular on the medial side, and the calcaneus and the cuboid on the lateral, the line of the joints to be opened would be one drawn across the dorsum from a point just behind the tuberosity of the navicular to a point corresponding to the calcaneo-cuboid joint, just midway between the tip of the lateral malleolus and the base of the fifth metatarsal bone. The convexity of the plantar flap should reach to a point 2.5 cm. (1 in.) behind the heads of the metatarsal bones. Owing to the tendency of the unbalanced action of the calf muscles to tilt up the calcaneus and thus throw the scar down into the line of pressure, the powerful tibialis anterior tendon and those of the extensors should be carefully stitched into the tissues of the sole flap.

In **Lisfranc's, or Hey's, or the tarso-metatarsal amputation,** the bases of the fifth and first metatarsals must be defined. The first of these can always be detected, even in a stout or swollen foot; on the medial side the joint between the first cuneiform and the first metatarsal

FIG. 1179.—VERTICAL SECTION THROUGH THE CUNEIFORM AND CUBOID BONES. (One-half.)



bone lies 3.7 cm. (1½ in.) in front of the navicular tuberosity. In opening the joint between the second metatarsal and the middle cuneiform, its position (the base of the former bone projecting upward on to a level 6 or 8 mm. (¼ or ⅓ in.) above the others), and the way in which it is locked in between its fellows and the cuneiform bones, must be remembered. The convexity of the plantar flap here reaches the heads of the metatarsal bones.

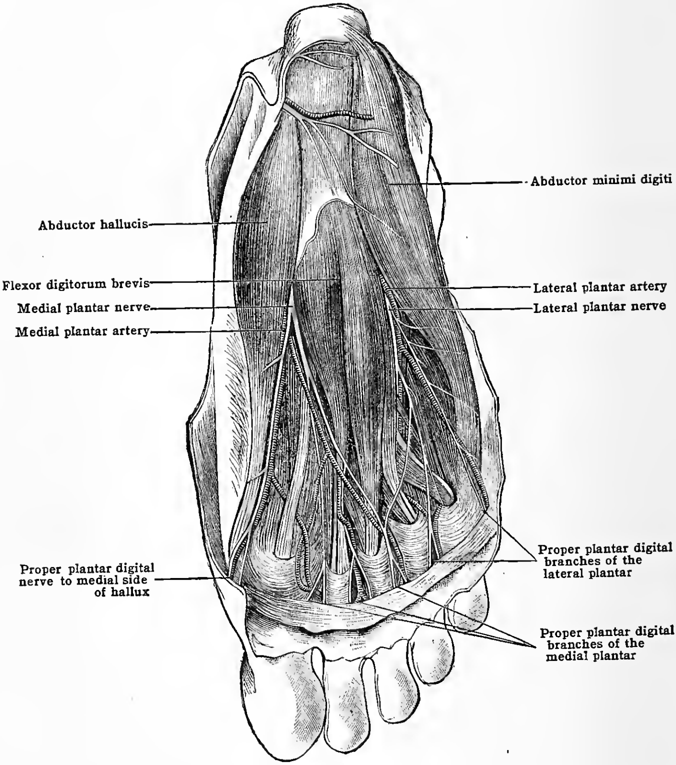
In marking out the flaps for the **amputation of the great toe,** the large size of the head of the first metatarsal, and the importance of leaving this so as not to diminish its supporting power and the treading width of the foot, and thus of marking out flaps sufficiently long and large, must be borne in mind. The dorsal incision should begin 3.7 cm. (1½ in.) above the web. The line of the joint is a little distal to the centre of the ball of the toe (fig. 1181). The sesamoid bones should be left, so as not to endanger the vitality of the flaps. In amputation of the other toes, the line of their metatarso-phalangeal joints lies a full inch above the web.

Bursæ and synovial membranes.—The synovial sheath of the extensor hallucis longus extends from the front of the ankle, over the instep, as far as the metatarsal bone of the great toe. There is generally a bursa over the instep, above, or it may be below, the tendon.

There is often an irregular bursa between the tendons of the extensor digitorum lougus and the projecting end of the talus over which the tendons play. There is much friction here. It is well to be aware that this bursa sometimes communicates with the joint of the head of the talus. (Holden.) There is a deep synovial bursa between the tendo Achillis and the calcaneus. Numerous other bursæ may appear over any of the bony points in the foot, especially when they are rendered over-prominent by morbid conditions.

Synovial membranes.—In addition to that of the ankle-joint, there are **six** synovial membranes in the **tarsus,** viz.:—(1) Talo-calcaneal, peculiar to these bones; (2) talo-calcaneo-navicular, common to these bones and the navicular; (3) between the calcaneus and the cuboid; (4) between the cuboid and the lateral two metatarsals; (5) between the first cuneiform and the first metatarsal; (6) a complicated and extensive one, which branches out between the navicular and cuneiform bones; between the cuneiforms; between the third cuneiform and the cuboid; between the second and third cuneiform and the second and third metatarsal bones; and between the second and third and the third and fourth metatarsal bones.

FIG. 1180.—SUPERFICIAL NERVES IN THE SOLE OF THE FOOT. (Ellis.)



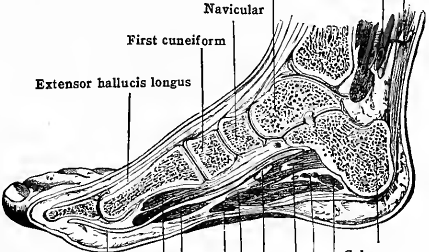
Dorsal artery.—The line of this is from the centre of the ankle-joint to the upper part of the first interosseous space.

On its medial side is the tendon of the extensor hallucis longus; on its lateral, the most medial tendon of the extensor digitorum longus. It is crossed by the most medial tendon of the extensor brevis. The origin of this muscle should be noted on the lateral and fore part of the calcaneus.

Cutaneous nerves (fig. 1182).—The sites of these, numerous on the dorsum of the foot, are as follows:—The **superficial peroneal (musculo-cutaneous) nerve,** having perforated the fascia in the lower third of the leg, divides into two chief branches, medial and lateral, which supply all the toes save the lateral part of the little, and the adjacent sides of the first and second. The **deep peroneal** becomes cutaneous in the first space, and is distributed to the contiguous sides of the above-mentioned toes. The **sural nerve** runs with the small saphenous vein below the malleolus, and supplies all the lateral border of the foot and the lateral side of the little toe. The **saphenous nerve,** coursing with the great saphenous vein in front of the medial malleolus, supplies the medial border of the foot as far as the middle of the instep. The cutaneous nerves to the sole (from the medial calcaneal, medial, and lateral plantar) are shown in fig. 1180.

Plantar arteries.—The line of the medial would be one drawn from the bifurcation of the posterior tibial, or about midway between the tip of the medial malleolus and the medial border of the heel, to the middle of the plantar surface of the great toe. The course of the lateral plantar runs in a line drawn from the bifurcation, first obliquely across the foot to a point a little medial to the medial side of the base of the fifth metatarsal, and thence obliquely across the foot till it reaches the first space and joins with a communicating branch from the dorsal artery. It thus crosses the foot twice. In the first part, it is more superficial, in the second

Fig. 1181.—Longitudinal Section of Foot. (One-third.) (Braune.)



very deep; it here forms the plantar arch, and is only separated from the bases of the metatarsals by the interossei.

The anastomosing branches about the ankle-joint are shown in figs. 1170 and 1171.

Tarsal bones.—The chief surgical points about these is the frequency with which they are diseased and their changes in talipes. **Frequency of disease.**—This is explained, chiefly, by their delicate structure and the fact that on the aspect in which they are most exposed to injury the soft parts are scanty. Disease once started, often by slight injury, finds in the terminal circulation of the parts, and the frequent want of rest, other contributing causes. The numerous and complicated synovial membranes mentioned above explain the extension of the disease. The calcaneus is the only bone in which mischief is likely to remain limited. The presence of an epiphysis to this bone appearing about the age of ten and joining at puberty is to be remembered as a starting-point of disease here. **Talipes.**—To take one instance, a case of talipes equino-varus, of congenital origin and confirmed degree, the following are the chief structural changes which should have been obviated and now have to be met, given briefly. *Calcaneus.*—This is elevated posteriorly, and rotated so that its long axis is directed obliquely medially. *Talus.*—The inclination of the neck medially is much increased, and the whole bone protruded from the ankle-joint. According to some, the neck is increased in length. *Navicular.*—This is displaced medially so that it articulates with the medial side of the head of the talus, and its tuberosity may form a facet on the medial malleolus. *Cuboid.*—The dorsal surface of this is displaced downward, and bears much of the pressure in walking. *Tendons.*—Those chiefly shortened are the tendo Achillis and those of the tibials and flexor digitorum longus. The tendo Achillis is displaced medially. *Ligaments.*—Those on the lateral side are stretched, those on the medial, especially the anterior part of the deltoid, the dorsal talo-navicular and the plantar calcaneo-navicular ligaments are shortened. The plantar fascia is also shortened, together with the abductor hallucis, which arises from it.

ARCHES OF THE FOOT

These are two—the **longitudinal** and the **transverse.**

(A) **Longitudinal arch** (fig. 1181).—This is by far the most important. **Extent:** From the heel to the heads of the metatarsal bones. The toes do not add much to the strength and elasticity of the foot. (Humphry.) They enlarge its area and adapt it to inequalities of the ground, are useful in climbing, and in giving an impulse to the step before the foot is taken from the ground, in the third stage of walking. **Two pillars.**—The late Professor Humphry laid stress on the important differences between these two:—(1) **Posterior pillar:** This consists of the calcaneus and hinder part of the talus, viz., only two bones in order to secure solidity, and to enable the calf-muscles to act directly upon the heel, without any of that loss of power which would be brought about by many moving joint-surfaces. (2) **Anterior pillar:** Here there are many bones and joints to provide (*a*) elastic springiness, and (*b*) width. This anterior pillar may again be divided into two: (*a*) A **medial pillar,** very elastic, consisting of the talus, navicular, three cuneiforms, and three medial metatarsals. (*b*) A **lateral,** formed by the cuboids and two lateral metatarsals. This is stronger and less elastic, and tends to buttress up the medial pillar. **Keystone:** This is represented by the summit of the trochlear surface of the talus.

It differs from the keystones in ordinary arches in the following important particulars (Humphry): (*a*) in not being wedge-shaped; (*b*) in not being so placed as to support and receive support from the two halves of the arch: in front the talus does fulfil this condition by fitting into the navicular; behind, it overlaps the calcaneus without at all supporting it; (*c*) this arch and the support of its keystone largely depend on ligaments and tendons; (*d*) it is a mobile keystone: to give it chances of shifting its pressure, and so obtaining rest, its equilibrium is not always maintained in one position.

(B) **Transverse arch** (fig. 1179).—This is best marked about the centre of the foot, at the instep, along the tarso-metatarsal joints. This, as well as the longitudinal arch, yields in walking, and so gives elasticity and spring.

Uses of the arches.—(1) They give combined elasticity and strength to the tread. Thus they give firmness, free quickness, and dignity, both in standing and walking, instead of what we see in their absence, viz., the lameness of an artificial limb, and the shuffling or hobbling which goes with tight boots, deformed toes, flat-foot, bunions, corns, etc.; (2) they protect the plantar vessels, nerves, and muscles; (3) they add to man's height; (4) they make his gait a perfect combination of plantigrade and digitigrade, as is seen in man's walking, when he uses first the heel, then all the foot, and then the toes. (Humphry.)

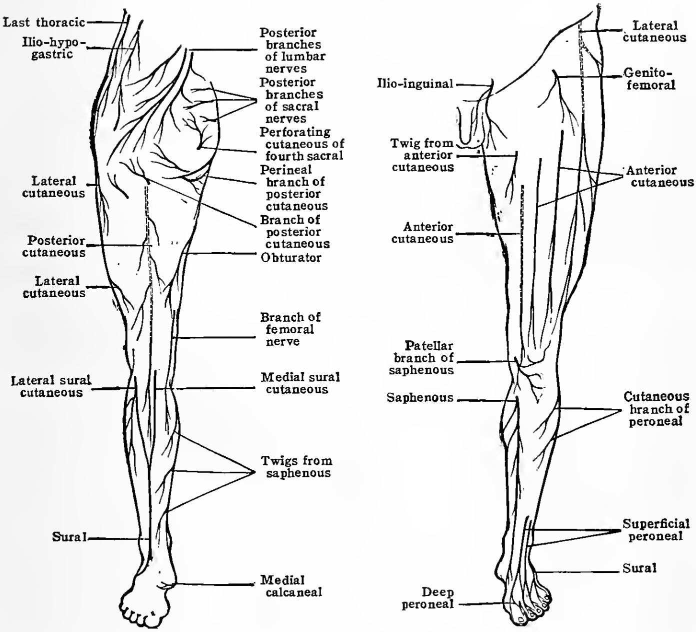
Maintenance of the arch.—(1) **Plantar fascia.**—This is (*a*) a binding tie between the pillars of the longitudinal arch; (*b*) it protects the structures beneath; (*c*) it is a self-regulating ligament and protection. Thus, having a quantity of muscular tissue attached to its upper and back part, is constantly responds by the contraction of this, to the amount of any pressure made upon the foot. (2) **Plantar calcaneo-navicular ligament.**—This is a thick tie-plate of fibro-cartilaginous tissue, partly elastic, hence called the 'spring-ligament,' attached to the anterior margin of the sustentaculum tali and under surface of navicular. It is thickest at its medial side, where it blends with the anterior part of the deltoid ligament, and below, where the tibialis posterior, passing into the sole, is in contact with the ligament and gives much support to the head of the talus and the navicular, while it assists the power and spring of this ligament (*vide infra*). The dropping of the talus and navicular and their projection on the medial side in flat-foot are largely due to the giving way of the above ligament. (3) **Calcaneo-cuboid ligaments.** (*a*) **Long;** (*b*) **short.**—These ligaments are the main support of the lateral, firm, and less elastic part of the longitudinal arch. (4) **Tibialis posterior.**—The reason of this muscle having so many insertions below is to brace together the tarsal bones, and to prevent their separation when, in treading, the elastic anterior pillar tends to widen out. Of these numerous offsets, that to the navicular is the most important. Thus it strengthens the calcaneo-navicular ligament by blending with it, and thus supports the arch at a trying time. By coming into action when the heel is raised, this tendon helps the calcaneo-navicular ligament to support the head of the talus, and to maintain the arch of the foot when the weight of the body is thrown forward on to the instep. In other words, the tibialis posterior comes into play just when the heaviest of its duties is devolving upon this ligament, viz., when the heel is being raised, and the body-weight is being thrown over the instep on to the opposite foot. (5) **Peroneus longus.**—This raises the lateral pillar, and steadies the lateral side of the arch. Further, by its strong process attached to the first metatarsal bone, it keeps the great toe strapped down firmly against the ground; thus, keeping down the anterior pillar of the longitudinal arch, it aids the firmness of the tread. (Humphry.) (6) **Tibialis anterior.**—This braces up the keystone of the arch. Thus, by keeping up the first cuneiform, it maintains the navicular, and so indirectly the talus *in situ*.

Fig. 1172 will remind the reader of the arrangement of the **superficial lymphatics of the lower extremity.** These follow chiefly the saphenous veins, and enter the inguinal nodes, except those from the lateral aspect of the heel which drain into the popliteal lymph-nodes. The superficial lymphatics of the buttock enter the lateral, and those over the adductor muscles the most medial group of the inguinal glands.

The deep lymphatics of the lower limb, comparatively few in number, follow the course of the deeper vessels. After passing through some four or five glands deeply placed about the popliteal vessels (these glands also receive the lymphatics along the small saphenous vein), the lymph is carried up by lymphatics along the femoral artery to the deep inguinal nodes; one very often occupies the femoral canal.

Fig. 1182 shows the distribution of the **superficial nerves** on both aspects of the limb.

FIG. 1182.—DISTRIBUTION OF CUTANEOUS NERVES ON THE POSTERIOR AND ANTERIOR ASPECTS OF THE INFERIOR EXTREMITY.



Paralysis of the nerves of the lower extremity.—The student should take this opportunity of considering from the surgical anatomy the results of paralysis of the nerve chiefly affected, viz., the great sciatic and its branches. *Sciatic:* The limb hangs flail-like, much in the position of one affected with advanced infantile paralysis. In addition to the results of paralysis of its two divisions, flexion at the knee will be lost, owing to paralysis of the hamstrings. *Peroneal* (*external popliteal*) *nerve:* The extensors and peronei being paralysed the foot drops, it cannot be dorsiflexed at the ankle nor abducted at the medio-tarsal joint. Adduction at the latter joint is impaired owing to paralysis of the tibialis anterior. The arch of the foot is largely lost owing to paralysis of the peroneus longus. Slight extension of the two distal phalanges of the four lateral toes is still possible by means of the interossei. Sensation is impaired over the distribution of the medial sural cutaneous deep, and superficial peroneal nerves. *Tibial* (*internal popliteal*) *nerve:* Here the calf muscles, the flexors, and the muscles of the sole of the foot are paralysed. The ankle cannot be plantar-flexed.
